Abstract

We review the essential characteristics of the three different approaches to specifying a sampling strategy; the design-based approach, the model-assisted approach and the model-based approach. We then describe a unified framework for survey design and estimation that incorporates all three approaches, allowing us to contrast them in terms of their concepts of efficiency as well as their robustness to assumptions about the characteristics of the finite population. Our conclusion is that although no one approach delivers both efficiency and robustness, the model-based approach seems to achieve the best compromise between these typically conflicting objectives.

Key Words¹: Model-based; Model-assisted; Design-based; Sample survey inference; Design-unbiased; Model-unbiased; Robust methods; Probability sampling; Balanced sampling.

¹ AMS Classification 62D05

1. INTRODUCTION

Sample survey theory is concerned with methods of sampling from a finite population of N units and then making inferences about finite population quantities on the basis of the sample data. A method of sampling coupled with a method of estimation given the sample data is often referred to as a *sampling strategy*, and typically corresponds to a set of rules which tell one how to obtain a sample of units from the finite population and then how to manipulate the resulting sample data to estimate the value of a quantity defined for the entire population.

In this paper we review the essential characteristics of the three different approaches to specifying a sampling strategy; the design-based approach, the model-assisted approach and the model-based approach. All three approaches are in use in major statistical agencies. Furthermore, the advantages and disadvantages of all three have been hotly debated in the sampling theory literature in recent years. See the sequence of papers Smith (1976), Smith (1984) and Smith (1994) for a clear and entertaining description of how this debate has progressed. However, with the exception of Brewer and Särndal (1983), there seems to have been little attempt to view all three approaches from a unified statistical perspective.

We describe such a unified framework for survey design and estimation below. After embedding the above three approaches in this common framework, we then contrast them in terms of their concepts of efficiency as well as their robustness to assumptions about the characteristics of the finite population. Our conclusion is that although no one approach delivers both efficiency and robustness, the model-based approach seems to achieve the best compromise between these typically conflicting objectives.

The paper is organised as follows. In the following section, some basic concepts of the statistical (as opposed to the practical) theory of sample design and estimation are introduced, along with the common distributional framework that underlies the development in the paper. In sections 3 through 5 this framework is used to characterise the statistical basis for choosing an efficient sampling strategy under the above three approaches. The paper concludes in section 6 with a discussion of how the different robustness concepts that apply within each

approach relate to one another within this framework, together with comments on the strengths and weaknesses of each.

2. BASIC CONCEPTS

A fundamental sample survey concept is that of a population *frame*. This is the list of the N units making up the finite population. Availability of a frame is a basic requirement underlying most (though not all) of sample survey theory, since sampling methods are usually expressed in terms of rules for deciding which elements of a list constitute the sample. Note that this frame requirement does not exclude multistage surveys from consideration, since these require access to an initial frame for selection of first stage units and then subsequent 'sub-frames' for selection of second and later stage units.

In what follows it will be assumed that the frame always contains a unique identifier or *label* for each unit of the population. In many cases the frame also contains the values of one or more *auxiliary* variables associated with each unit of the finite population. We use the index i (and sometimes j and k as well) to denote the population labels. Without loss of generality we can assume these labels take the values 1, 2, ..., N , so it makes sense to refer to the i^{th} population unit.

For simplicity we also assume in this paper that there is only one auxiliary variable, X and one survey variable Y . We put X_i equal to the value of X for the i^{th} population unit, with Y_i defined similarly. The extension to multiple Y -variables and multiple X -variables does not involve introduction of new concepts, but does make the notation much more complex.

A traditional objective of most surveys is estimation of the finite population total,

$$T_Y = \sum_{i=1}^N Y_i .$$

In order to estimate T_Y , the survey sampler (who is assumed to have access to the population frame) selects a sample of units from the population by identifying their labels on the frame, and then measures their corresponding values of Y . These sample values of Y are then combined with framework information to generate the required estimate of T_Y .

A convenient way of characterising this sample selection process is to assume that, for each unit i on the frame, the survey sampler generates a new variable S which takes a value equal to the number of times that particular population unit's Y value is observed. The set of labels corresponding to population units that are sampled in this way is $s = \{i; S_i > 0\}$. The labels of the remaining non-sampled population units then define the set $r = \{i; S_i = 0\}$.

The distribution of these S_i values effectively defines what is generally referred to as the *design* of the sample survey. In principle at least, the survey sampler has complete control over (and hence complete knowledge of) this distribution. Let \mathbf{S} denote the vector valued random variable corresponding to the N population values of S_i and let \mathbf{X} denote the corresponding N -vector of population values of the X_i .

Throughout, we assume that the distribution of \mathbf{S} only depends on the known population values in \mathbf{X} . That is, given \mathbf{X} , the distribution of \mathbf{S} is completely specified. This assumption is often referred to as *non-informative* sampling in the literature (e.g. Pfeffermann 1993). An immediate consequence is that, given \mathbf{X} , the distributions of \mathbf{S} and \mathbf{Y} , the population N -vector of Y values, are independent. Note that this assumption is not appropriate in cases where the sampler has limited or no control over the sampling process, since in those cases there is the possibility of selection bias, and consequent dependence between the distributions of \mathbf{Y} and \mathbf{S} , even after conditioning on \mathbf{X} . See Smith (1983) and Sugden and Smith (1984).

This characterisation of the outcome of sample selection as a random vector \mathbf{S} includes probability sampling as a special case. However, since there is no requirement that the distribution of \mathbf{S} be non-degenerate, it also includes many so-called 'non-random' (strictly speaking non-probability sampling based) selection methods used by survey practitioners.

Turning now to estimation of T_Y , we see that any estimator of this quantity can only be based on the available data, i.e. the observed sample values of Y together with relevant frame information (the population values of X and S). Consequently, we consider a general linear estimator of T_Y of the form

$$\hat{T}_Y = \sum_{i \in s} W_i(\mathbf{S}, \mathbf{X}) Y_i$$

where $W_i(\mathbf{S}, \mathbf{X})$ is a weight associated with sampled population unit i . Observe that this weight generally depends on the other sampled units since it depends on \mathbf{S} and \mathbf{X} . Also, we can equivalently write

$$\hat{T}_Y = \sum_{i=1}^N W_i(\mathbf{S}, \mathbf{X}) S_i Y_i$$

since $S_i = 0$ for non-sampled population units.

In general, we can think of the values of the $W_i(\mathbf{S}, \mathbf{X})$ as characterising the estimation process in the same way that the values S_i characterised the sampling process. That is, the survey sampler can be considered as in principle defining a value $W_i(\mathbf{S}, \mathbf{X})$ for each population unit (whether sampled or not). The value of this weight variable W may depend on the population values of the auxiliary variable, X , and those of the selection variable, S , but not those of the survey variable Y . That is, if we put \mathbf{W} equal to the population vector defined by the $W_i(\mathbf{S}, \mathbf{X})$, then \mathbf{W} is a random vector whose distribution is completely determined by that of \mathbf{S} and \mathbf{X} . To keep our notation simple, we drop explicit referencing to \mathbf{S} and \mathbf{X} when writing down individual weights from now on, writing $W_i = W_i(\mathbf{S}, \mathbf{X})$ in what follows. In all cases, however, the reader should keep in mind the dependence of these weights on the realised values of \mathbf{S} and \mathbf{X} .

A *sampling strategy* corresponds to the pair (\mathbf{S}, \mathbf{W}) . Deciding on a sampling strategy therefore consists of (i) given \mathbf{X} , choosing an appropriate distribution for \mathbf{S} , and (ii) given \mathbf{X} and the distribution generated under (i), choosing an appropriate specification for \mathbf{W} . In the following sections we compare and contrast three different approaches to carrying out (i) and (ii) above. In particular, we focus on choice of an optimal strategy in each case.

Finally, we observe that in all cases, the inferential framework assumed is the one defined by the joint distribution of \mathbf{S} , \mathbf{X} and \mathbf{Y} . That is, the sample space for inference is the one corresponding to all possible realisations of these three vectors. Consequently, all

relevant probabilities are defined with respect to this joint distribution, as are expectations and variances (both conditional and unconditional).

3. OPTIMALITY UNDER THE DESIGN-BASED APPROACH

This approach has its origin in Neyman's key paper (Neyman, 1934). It also represents the basic underlying philosophy in most traditional sampling theory texts, e.g. Cochran (1977), Kish (1965). A key concept under this approach is that of *design unbiasedness*. That is, for any choice of sampling process S , the weighting process W must be such that the frequency weighted average value of \hat{T}_Y over all possible samples generated under S is the actual value of T_Y . In other words, this approach restricts consideration to those weights \mathbf{W} which ensure that

$$E(\hat{T}_Y - T_Y | \mathbf{X}, \mathbf{Y}) = 0 \quad (1)$$

for all values of \mathbf{Y} and \mathbf{X} .

For (1) to hold for arbitrary \mathbf{Y} and \mathbf{X} we must have

$$E(W_i S_i | \mathbf{X}, \mathbf{Y}) = 1$$

or, since the distributions of both \mathbf{S} and \mathbf{W} are completely determined by that of \mathbf{X} ,

$$E(W_i S_i | \mathbf{X}) = 1.$$

A sufficient condition for this to be satisfied is clearly where

$$W_i^{-1} = E(S_i | \mathbf{X}) \quad (2)$$

in which case

$$\hat{T}_Y = \sum_{i \in s} \frac{S_i Y_i}{E(S_i | \mathbf{X})}. \quad (3)$$

The design-based approach requires that all inferential probabilities be conditioned on both \mathbf{Y} and \mathbf{X} . Consequently, under this approach the efficiency of \hat{T}_Y is measured by

$$\text{Var}(\hat{T}_Y - T_Y | \mathbf{X}, \mathbf{Y}) = \text{Var}(\hat{T}_Y | \mathbf{X}, \mathbf{Y}) = \text{Var}\left(\sum_{i=1}^N W_i S_i Y_i | \mathbf{X}, \mathbf{Y}\right) = \sum_{i=1}^N \sum_{j=1}^N \text{Cov}(W_i S_i, W_j S_j | \mathbf{X}) Y_i Y_j$$

which, in the case of the weighting method (2) above, becomes

$$\text{Var}(\hat{T}_Y - T_Y | \mathbf{X}, \mathbf{Y}) = \sum_{i=1}^N \sum_{j=1}^N \frac{\text{Cov}(S_i, S_j | \mathbf{X})}{E(S_i | \mathbf{X})E(S_j | \mathbf{X})} Y_i Y_j. \quad (4)$$

In some circumstances (e.g. where a particularly complex sampling method has been employed) it may be impossible to evaluate (2) exactly. In such cases condition (1) is at least approximately true whenever

$$W_i^{-1} = \hat{E}(S_i | \mathbf{X}) \quad (5)$$

where \hat{E} denotes an estimate of the conditional regression function, based on the frame values of X . In this case the bias of the resulting estimator \hat{T}_Y under the design-based approach is

$$E(\hat{T}_Y - T_Y | \mathbf{X}, \mathbf{Y}) = \sum_{i=1}^N \left(\frac{E(S_i | \mathbf{X})}{\hat{E}(S_i | \mathbf{X})} - 1 \right) Y_i \quad (6)$$

with variance

$$\text{Var}(\hat{T}_Y - T_Y | \mathbf{X}, \mathbf{Y}) = \sum_{i=1}^N \sum_{j=1}^N \frac{\text{Cov}(S_i, S_j | \mathbf{X})}{\hat{E}(S_i | \mathbf{X})\hat{E}(S_j | \mathbf{X})} Y_i Y_j. \quad (7)$$

The measure of efficiency of \hat{T} in this case is therefore its design-based mean squared error

$$\begin{aligned} \text{MSE}(\hat{T}_Y | \mathbf{X}, \mathbf{Y}) &= \text{Var}(\hat{T}_Y | \mathbf{X}, \mathbf{Y}) + E^2(\hat{T}_Y - T_Y | \mathbf{X}, \mathbf{Y}) \\ &= \sum_{i=1}^N \sum_{j=1}^N \left\{ \frac{\text{Cov}(S_i, S_j | \mathbf{X})}{\hat{E}(S_i | \mathbf{X})\hat{E}(S_j | \mathbf{X})} + \left(\frac{E(S_i | \mathbf{X})}{\hat{E}(S_i | \mathbf{X})} - 1 \right) \left(\frac{E(S_j | \mathbf{X})}{\hat{E}(S_j | \mathbf{X})} - 1 \right) \right\} Y_i Y_j \\ &= \sum_{i=1}^N \sum_{j=1}^N \left[\frac{E\left\{ (S_i - \hat{E}(S_i | \mathbf{X})) (S_j - \hat{E}(S_j | \mathbf{X})) | \mathbf{X} \right\}}{\hat{E}(S_i | \mathbf{X})\hat{E}(S_j | \mathbf{X})} \right] Y_i Y_j. \end{aligned} \quad (8)$$

It is straightforward to show that if \hat{E} actually recovers $E(S_j | \mathbf{X})$, then (8) reduces to the earlier expression (4) for the design variance of \hat{T} .

We do not explore specification of \hat{E} in this paper, beyond noting that many standard weighting methods, including post-stratification and ratio estimation, are special cases. For example, ratio estimation can be characterised as replacing $E(S_i | \mathbf{X})$ by the weighted average

$$\hat{E}(S_i | \mathbf{X}) = \frac{\sum_{j=1}^N X_j S_j}{\sum_{j=1}^N X_j}.$$

Irrespective of whether the W_i are defined via (2) or via (5), the 'classic' design-based approach to choosing an optimal sampling strategy is to choose an appropriate distribution for \mathbf{S} in order to make the mean squared error (8) above as small as possible, subject usually to a restriction on the sample size, or more generally, on the sum of the components of \mathbf{S} .

Where no restriction is placed on \mathbf{Y} , this is an impossible task - a result first noted by Godambe (1955). A short proof of this famous non-existence result, essentially based on Basu (1971) goes as follows: Consider the population defined by $Y_1 > 0$ and $Y_j = 0, j \neq 1$. In this case (4) is zero (and so our strategy is efficient) if we select our sample so that $Pr(S_1 = 1 | \mathbf{X}) = 1$, so $E(S_1 | \mathbf{X}) = 1$, and use the weighting scheme (2). In particular, this strategy remains efficient when we impose the further restriction $Pr(S_2 = 1 | \mathbf{X}) = 0$. However, this restricted strategy is no longer optimal if we apply it to another population where $Y_2 > 0$ and $Y_j = 0, j \neq 2$. Consequently, no globally optimal sampling strategy exists under the design-based approach. Each sampling strategy needs to be looked at anew, since there is no 'gold standard' against which it can be compared.

4. OPTIMALITY UNDER THE MODEL-ASSISTED APPROACH

As the preceding paragraph makes clear, the main problem with the design-based approach to finding an optimal sampling strategy is that it is far too general. By specifying efficiency criteria in terms of the conditional distribution of \hat{T}_Y given \mathbf{X} and \mathbf{Y} , this approach paints itself into a corner. As a consequence, almost from the very beginning of large scale application of design-based theory in survey sampling, practitioners have adopted strategies which have small design mean squared error for those realisations of \mathbf{Y} which are, in some sense, *reasonable*.

In practice, such values of \mathbf{Y} are typically defined by assuming a *model* for the distribution of \mathbf{Y} given \mathbf{X} . That is, practitioners have been willing to use models in order to *identify* optimal strategies for estimating T_Y . However, their assessment of these strategies has remained design-based.

4.1 Model-Assisted Strategies That Are Also Design-Unbiased

The model-assisted approach is comprehensively discussed in Särndal, Swensson and Wretman (1992). Typically, the approach still assumes that the weighting variable W at least approximately satisfies (2). That is, the resulting estimator \hat{T}_Y is design-unbiased, or approximately so. However, rather than attempting to specify the distribution of the sample design variable S by minimising the design mean squared error (8) for all possible values of \mathbf{Y} , the model-assisted approach seeks to minimise the expectation of this quantity given \mathbf{X} . That is, we seek a distribution for \mathbf{S} which minimises the average value of (8) over those \mathbf{Y} values 'consistent with' the known values in \mathbf{X} .

From (8) we see that this expected design-based mean squared error can be written

$$E\left[MSE(\hat{T}_Y | \mathbf{X}, \mathbf{Y}) | \mathbf{X}\right] = \sum_{i=1}^N \sum_{j=1}^N \left[\frac{E\left\{ (S_i - \hat{E}(S_i | \mathbf{X})) (S_j - \hat{E}(S_j | \mathbf{X})) | \mathbf{X} \right\}}{\hat{E}(S_i | \mathbf{X}) \hat{E}(S_j | \mathbf{X})} \right] E(Y_i Y_j | \mathbf{X}). \quad (9)$$

Given a specification for the first and second order moments of \mathbf{Y} given \mathbf{X} , (9) can be minimised, and an optimal sample design (and hence optimal sampling strategy) obtained. To illustrate, consider the case where the X_i are strictly positive and the regression of Y on X is linear and through the origin. That is

$$\begin{aligned} E(Y_i | \mathbf{X}) &= \beta X_i \\ \text{Var}(Y_i | \mathbf{X}) &= \sigma_i^2 \\ \text{Cov}(Y_i, Y_j | \mathbf{X}) &= 0; i \neq j. \end{aligned} \quad (10)$$

Then, when the weights W_i are determined by (2),

$$E\left[MSE(\hat{T}_Y | \mathbf{X}, \mathbf{Y}) | \mathbf{X}\right] = \sum_{i=1}^N \left[\frac{\text{Var}(S_i | \mathbf{X})}{E^2(S_i | \mathbf{X})} \right] \sigma_i^2 + \beta^2 \sum_{i=1}^N \sum_{j=1}^N \left[\frac{\text{Cov}(S_i, S_j | \mathbf{X})}{E(S_i | \mathbf{X}) E(S_j | \mathbf{X})} \right] X_i X_j.$$

To make things even simpler, we restrict ourselves further to the case of Poisson sampling. Here S_i is either one or zero, with the i^{th} population unit either included into or excluded from the sample according to the outcome of an independent Bernoulli trial with success probability $\pi_i = E(S_i | \mathbf{X})$. Consequently

$$\text{Var}(S_i | \mathbf{X}) = E(S_i | \mathbf{X})[1 - E(S_i | \mathbf{X})] = \pi_i(1 - \pi_i)$$

and, for $I \neq J$

$$\text{Cov}(S_i, S_j | \mathbf{X}) = 0.$$

The expected design-based mean squared error for this case is therefore

$$E[MSE(\hat{T}_Y | \mathbf{X}, \mathbf{Y}) | \mathbf{X}] = \sum_{i=1}^N \left(\frac{1}{\pi_i} - 1 \right) (\sigma_i^2 + \beta^2 X_i^2).$$

This expression is minimised, subject to the expected sample size constraint

$$\sum_{i=1}^N \pi_i = n$$

when

$$\pi_i = n \frac{\sqrt{\sigma_i^2 + \beta^2 X_i^2}}{\sum_{j=1}^N \sqrt{\sigma_j^2 + \beta^2 X_j^2}}. \quad (11)$$

Observe that when σ_i is proportional to X_i this optimal sample inclusion probability is proportional to X_i . Furthermore, for $\sigma_i \gg \beta$, these optimal probabilities are approximately nN^{-1} . That is, in cases where the regression effect in (10) is insignificant, a strategy that has equal first order inclusion probabilities is indicated.

4.2 Model-Assisted Strategies That Are Design-Unbiased On Average

The requirement that \hat{T}_Y be design-unbiased (or approximately design-unbiased) that was imposed in section 4.1 is rather strong. An appealing extension of the model-assisted approach, whose motivation follows along the same lines as those leading to the use of the average mean squared error (9), is discussed in Brewer (1995). This replaces the design-

unbiasedness requirement by the weaker requirement that the design bias of \hat{T}_Y averages out to zero over possible values of Y . That is, rather than *exact* (or approximate) design unbiasedness, one requires *average* design-unbiasedness, or

$$E(\hat{T}_Y - T_Y | \mathbf{X}) = E(E(\hat{T}_Y - T_Y | \mathbf{X}, \mathbf{Y}) | \mathbf{X}) = 0. \quad (12)$$

Clearly, exact design-unbiasedness implies average design-unbiasedness. However, as we shall see in section 5.1, there are many other design-biased strategies which also satisfy (12). Consequently, this condition is rather weak. Under the regression model (10) for \mathbf{Y} , it translates as

$$\begin{aligned} E\left(E\left(\sum_{i=1}^N (W_i S_i - 1) Y_i | \mathbf{Y}, \mathbf{X}\right) | \mathbf{X}\right) &= E\left(\sum_{i=1}^N (E(W_i S_i | \mathbf{X}) - 1) Y_i | \mathbf{X}\right) \\ &= \beta \sum_{i=1}^N (E(W_i S_i | \mathbf{X}) - 1) X_i \\ &= 0 \end{aligned}$$

or

$$\sum_{i=1}^N E(W_i S_i | \mathbf{X}) X_i = \sum_{i=1}^N X_i.$$

There is no unique solution to this identity. In particular, all three of the following weighting methods satisfy it.

$$W_i = \frac{\sum_{j=1}^N X_j}{\sum_{j=1}^N E(S_j | \mathbf{X}) X_j} \quad (13)$$

$$W_i = \frac{\sum_{j=1}^N X_j}{\sum_{j=1}^N S_j X_j} \quad (14)$$

and

$$W_i = \frac{\sum_{j=1}^N X_j}{E(S_i | \mathbf{X}) \sum_{j=1}^N \frac{S_j X_j}{E(S_j | \mathbf{X})}}. \quad (15)$$

Note that the weights (13) and (14) do not depend on i . Furthermore (13) is the same for any realisation of \mathbf{S} . In an asymptotic (large N , large n , small n/N) sense, the weights defined by (13) and (14) are essentially the same, so an asymptotic analysis will lead to the same optimal sample design for both these weighting systems, provided one exists. Also, since

$$E\left[\sum_{j=1}^N \frac{S_j X_j}{E(S_j | \mathbf{X})} \mid \mathbf{X}\right] = \sum_{j=1}^N X_j$$

it follows that a similar asymptotic analysis indicates the weights defined by (15) and (2) are equivalent, so, in the case of the regression model (10) and Poisson sampling, the asymptotically optimal design under (15) is specified by the inclusion probabilities (11).

A large sample optimal sample design under either (13) or (14) can be obtained. As usual we assume the regression model (12) and Poisson sampling. Then

$$\begin{aligned} E\left(MSE(\hat{T}_y \mid \mathbf{Y}, \mathbf{X}) \mid \mathbf{X}\right) &= \sum_{i=1}^N \text{Var}(W_i S_i \mid \mathbf{X})(\sigma_i^2 + \beta^2 X_i^2) + \sum_{i=1}^N \left\{E(W_i S_i \mid \mathbf{X}) - 1\right\}^2 \sigma_i^2 \\ &= \bar{\pi}^{-2} \left[\sum_{i=1}^N \pi_i (1 - \pi_i)(\sigma_i^2 + \beta^2 X_i^2) + \sum_{i=1}^N (\pi_i - \bar{\pi})^2 \sigma_i^2 \right] \end{aligned}$$

where

$$\bar{\pi} = \left(\sum_{i=1}^N X_i \right)^{-1} \sum_{i=1}^N \pi_i X_i .$$

Provided s_i/X_i does not increase with X_i , this average mean squared error is minimised by choosing a sample design that makes $\bar{\pi}$ as large as possible, subject to the usual sample size constraint. Such an optimal sample design is easily seen to be the extreme design that sets $p_i = 1$ for the n units in the population with largest values of X , and $p_i = 0$ for the remaining $N-n$ population units.

4.3 The Robustness-Efficiency Tradeoff

If efficiency is the sole criterion for choice of a strategy and the assumed regression model (10) holds for the population being surveyed, then using the extreme sample design with weights defined by either (13) or (14) should lead to a much smaller average mean squared error than the more traditional design (11) with weights defined by either (2) or (15).

However, most users of the model-assisted approach would prefer the strategy specified by (11) and (15). In general, their main argument for this is that the weights (15), unlike (13) and (14), lead to an approximately design-unbiased estimator (since they approximate the exactly design-unbiased weights (2)), and consequently the sampling strategy specified by (11) and (15) is more 'robust' to model misspecification than the strategy specified by the extreme design consisting of those n units with largest X -values, coupled with the weights specified by (13) or (14).

Since any model assumption is inevitably wrong, this argument, on the surface at least, seems reasonable. However, it is important to realise that the 'robustness' achieved by design-unbiasedness is a repeated sampling property. There is no guarantee that a sample generated via (11) and using the (approximately) design-unbiased weights (15) will result in an estimate that is more *accurate* than the estimates obtained using the design-biased weights (13) or (14) for the same sample. This issue is discussed in more detail in section 6.

5. EFFICIENCY UNDER THE MODEL-BASED APPROACH

As the discussion in the previous two sections has made clear, the concept of design-unbiasedness is crucial to both the design-based as well as the model-assisted approaches to defining a sampling strategy. However, under the model-based approach this basic requirement is abandoned. The argument for doing so is straightforward. Since the distributions of both \mathbf{S} and \mathbf{W} are completely known once \mathbf{X} is known, their realisations contribute no information about \mathbf{Y} (and functions of \mathbf{Y} , like T_Y) over and above that already provided by \mathbf{X} . That is, once \mathbf{X} is known, \mathbf{S} and \mathbf{W} become *ancillary* statistics for inference about \mathbf{Y} . Consequently, application of the Conditionality Principle (Cox and Hinkley, 1974) leads to the conclusion that any inference about T_Y should be conditioned on \mathbf{S} and \mathbf{W} . Since design-unbiasedness does not condition on these values (averaging in fact over all possible realisations of these statistics), it is an inappropriate criterion to apply to the estimator \hat{T}_Y .

Brewer (1963) was one of the earliest (if not *the* earliest) researchers to seriously explore the implications of the model-based approach to survey inference. However, the most

important ideas underpinning this approach are due to the work of Richard Royall and his students. An elegant summary of the philosophy behind this approach is set out in Royall (1976). Since design-unbiasedness is no longer a requirement, the obvious alternative property we require of \hat{T}_Y under this approach is that it be *model-unbiased*. That is,

$$E(\hat{T}_Y - T_Y | \mathbf{S}, \mathbf{X}) = 0. \quad (16)$$

In other words, the values of the estimation errors $\hat{T}_Y - T_Y$ obtained for all population realisations \mathbf{Y} consistent with the actual value of \mathbf{X} observed, and the sample \mathbf{S} actually obtained, should average out to zero. The natural measure of the accuracy of \hat{T}_Y under this approach is then the variance of $\hat{T}_Y - T_Y$ given \mathbf{S} and \mathbf{X} .

In the context of the regression model (10), and assuming that \hat{T}_Y is a general linear estimator, the model-unbiasedness condition (16) becomes

$$\sum_{i=1}^N (W_i S_i - 1) X_i = 0 \quad (17)$$

and an optimal sample design is then one that ensures the conditional variance

$$\text{Var}(\hat{T}_Y - T_Y | \mathbf{S}, \mathbf{X}) = \sum_{i=1}^N (W_i S_i - 1)^2 \sigma_i^2 = \sum_{i=1}^N \{ \Delta(S_i > 0) (W_i S_i - 1)^2 + \Delta(S_i = 0) \} \sigma_i^2 \quad (18)$$

is as small as possible. Here Δ denotes the indicator function that takes the value 1 if its argument is true and is zero otherwise.

Note that the variance criterion (18) does not depend on weights for nonsampled units. Consequently, these can be set to zero. The optimal weights for the sampled units are obtained by minimising (18) subject to (17). These turn out to be of the form

$$W_i = \frac{1}{S_i} \left\{ \frac{X_i}{\sigma_i^2} \left[\frac{\sum_{j=1}^N \Delta(S_j = 0) X_j}{\sum_{j=1}^N \Delta(S_j > 0) \frac{X_j^2}{\sigma_j^2}} \right] + 1 \right\} \quad (19)$$

and it is straightforward to show that in this case

$$\hat{T}_Y = \sum_{i \in S} Y_i + \frac{\sum_{i \in S} \frac{Y_i X_i}{\sigma_i^2}}{\sum_{i \in S} \frac{X_i^2}{\sigma_i^2}} \sum_{i \in R} X_i$$

which is the best linear unbiased predictor (BLUP) of T_Y under the model (10).

The final step in finding an optimal model-based sample design is to identify the distribution for \mathbf{S} that minimises (18) when \mathbf{W} is defined by (19). Since in this case

$$\text{Var}(\hat{T}_Y - T_Y | \mathbf{S}, \mathbf{X}) = \frac{\left(\sum_{i=1}^N \Delta(S_i = 0) X_i \right)^2}{\sum_{i=1}^N \Delta(S_i > 0) \frac{X_i^2}{\sigma_i^2}} + \sum_{i=1}^N \Delta(S_i = 0) \sigma_i^2$$

it is not difficult to see that, provided X_i / σ_i is non-increasing in X_i , the optimal sample design is the extreme design (i.e. the one that selects the n units with largest X -values).

5.1 Model Unbiased Is Also Average Design Unbiased

It is interesting to observe that, for any set of model-unbiased weights, (16) implies

$$E(\hat{T}_Y - T_Y | \mathbf{X}) = E(E(\hat{T}_Y - T_Y | \mathbf{S}, \mathbf{W}, \mathbf{X}) | \mathbf{X}) = 0$$

and so all such weighting methods are also average design-unbiased, see (12). Furthermore,

$$\begin{aligned} E[MSE(\hat{T}_Y | \mathbf{X}, \mathbf{Y}) | \mathbf{X}] &= E\left[E\left((\hat{T}_Y - T_Y)^2 | \mathbf{X}, \mathbf{Y} \right) | \mathbf{X} \right] \\ &= E\left[(\hat{T}_Y - T_Y)^2 | \mathbf{X} \right] \\ &= E\left[E\left((\hat{T}_Y - T_Y)^2 | \mathbf{S}, \mathbf{W}, \mathbf{X} \right) | \mathbf{X} \right] \\ &= E\left[\text{Var}(\hat{T}_Y - T_Y | \mathbf{S}, \mathbf{W}, \mathbf{X}) | \mathbf{X} \right]. \end{aligned}$$

Since the conditional variance inside the square brackets in the last expression above is minimised whenever the extreme sample is chosen, it follows that the optimal model-based design for \hat{T}_Y under (10) also minimises the average mean squared error of this estimator.

That is, the optimal model-based design for \hat{T}_Y under (10) is also the optimal design for this estimator under the average design-unbiased approach of section 4.2.

5.2 The Robustness-Efficiency Tradeoff Revisited: Cosmetic Estimation

If one accepts (a) that any estimator for T_Y has to be based on a model for Y ; and (b) that some form of (approximate) design-unbiasedness is necessary for the model-robustness of this estimator, then an attractive option is to choose a model-assisted estimator that is (approximately) design-unbiased, but has the same 'look and feel' as an efficient model-unbiased estimator. This approach has been called *cosmetic estimation* by Särndal and Wright (1984). See Brewer (1999) for a thorough exploration of this idea in the context of a linear model for the population of interest. The obvious implication of cosmetic estimation is that one needs to include an extra estimating equation (or constraint) in the equations used to estimate the model parameters in order to ensure the cosmetic property. This means that the parameters of the working model are not estimated as efficiently as would be the case if one used the most efficient model-based estimators of these parameters. In the context of the simple linear model (10) and without replacement sampling, an efficient model-based estimator is

$$\hat{T}_Y(\hat{\beta}) = \sum_{i=1}^N \left\{ \Delta(S_i = 1)Y_i + \{1 - \Delta(S_i = 1)\} \hat{\beta}X_i \right\} = \sum_{i=1}^N \hat{\beta}X_i + \Delta(S_i = 1)(Y_i - \hat{\beta}X_i)$$

where $\hat{\beta}$ is an efficient estimator of β . In particular, when $\hat{\beta}$ is the ratio of the sample means of Y and X , $\hat{T}_Y(\hat{\beta})$ is then the most efficient linear predictor of T_Y under (10). However, from a model-assisted perspective, (10) leads to a generalized regression estimator of the form

$$\tilde{T}_Y(\hat{\beta}) = \sum_{i=1}^N \left\{ \hat{\beta}X_i + \pi_i^{-1} \Delta(S_i = 1)(Y_i - \hat{\beta}X_i) \right\} = \hat{T}_Y(\hat{\beta}) + \sum_{i \in s} (\pi_i^{-1} - 1)(Y_i - \hat{\beta}X_i)$$

where now $\hat{\beta}$ is chosen to be (at least asymptotically) a design-unbiased estimator of the ratio of the population means of Y and X . Cosmetic estimation then requires that $\hat{T}_Y(\hat{\beta})$ and $\tilde{T}_Y(\hat{\beta})$ be the same estimator, which in turn requires that

$$\hat{\beta} = \frac{\sum_{i \in s} (\pi_i^{-1} - 1) Y_i}{\sum_{i \in s} (\pi_i^{-1} - 1) X_i}.$$

In the general case where the sample inclusion probabilities vary from individual to individual in the sample this estimator can be an inefficient estimator of β , and hence lead to the cosmetic estimator $\tilde{T}_y(\hat{\beta})$ also becoming inefficient. The exception is where the π_i^{-1} do not vary between different sample units, in which case the cosmetic estimator and the most efficient model-based estimator are identical.

6. CHOOSING A ROBUST STRATEGY

So far we have concentrated on choice of an optimal strategy (if one exists) separately for each of the three approaches considered in this paper. In practice, however, one has to make a choice between these approaches for any particular application. How does one choose between the design-based, model-assisted and model-based approaches to identifying a sampling strategy in such a case? One criterion that is often invoked in making such a choice is that of *robustness*. We choose the approach that leads to robust inference (i.e. inference that is somehow not strongly tied to assumptions about the conditional distribution of \mathbf{Y} given \mathbf{X}), and, within the chosen approach identify an optimal strategy.

Now, from the design-based point of view, robustness is a non-issue, since inference under this approach does not need to model the conditional distribution of \mathbf{Y} given \mathbf{X} . Consequently, a naive user might argue that its nonparametric nature makes the design-based approach the obvious methodology for choosing a sampling strategy. However, as we have seen earlier, this choice leads nowhere since there are no relevant optimality criteria that can be checked under this approach. If one wants both robustness and optimality, one must turn to the model-assisted and model-based approaches.

Both of these recognise that one has to model the distribution of a survey variable Y in terms of available frame information (X) in order to decide on a strategy. Where these two approaches diverge, however, is on the meaningfulness of imposing the requirement that the sampling strategy adopted be design-unbiased (or at least approximately so). In particular, the

model-assisted approach claims robustness as a consequence of imposing (exact or approximate) design-unbiasedness.

6.1 Robustness And Design-Unbiasedness

The basic argument behind the imposition of design-unbiasedness (exact or, more usually, approximate) is that of robustness of validity. One allows the model to dictate the type of sample selected, but one does not allow it to also dictate the type of weighting method used.

The weights are typically constrained so that the average value of the estimator \hat{T}_Y under repeated sampling is equal to, or is approximately equal to, the population total of Y *no matter what model actually holds for Y in the population of interest*. In the words of a colleague and staunch believer in the model-assisted approach (Ken Brewer), adopting the model-assisted approach is like wearing both a belt and braces to hold up one's trousers. If the belt (the model) should break, then one is not going to be totally embarrassed, since the braces (design-unbiasedness) should still keep things in place.

From a model-based point of view, however, this robustness argument is unconvincing. Since, as has already been pointed out, design-unbiasedness is not a property associated with any particular sample, but rather one obtained by averaging over repeated samples, there does not appear to be any reason to believe that imposition of design-unbiasedness *on its own* is sufficient to somehow protect the survey analyst from a large estimation error (due to model misspecification for example) in any particular sample. A very large positive error associated with sample 1 can be cancelled out by a corresponding large negative error associated with sample 2. 'On average' things are fine, but for any particular sample they may be terrible. One has only to remember Basu's elephant fable (Basu, 1971) to realise how foolish complete reliance on design-unbiasedness can be.

The standard counter argument to this criticism is that in large samples, the use of probability sampling methods allows the law of large numbers to be invoked, ensuring that a design-unbiased (or approximately design-unbiased) estimator will converge to the true value of T_Y . Consequently the robustness property is really a *large sample* property. While this

observation is certainly true, it also assumes that the survey analyst is only interested in large sample inference. It also fails to mention how large is 'large'. Central limit behaviour may require sample sizes considerably greater than the survey designer can afford. Furthermore, it leaves wide open the question of appropriate sample design for small to medium sample sizes. Many modern survey collections are run under very tight budgets, ruling out large sample sizes. Sample designs for these collections rely on design-unbiasedness at their peril, and modern model-based designs are increasingly being used in these cases in an effort to maximise estimation efficiency.

6.2 Model-Based Is Not Model-Dependent

As we saw in the preceding section, the model-based approach can lead to extreme samples when taken to its logical conclusion. This has led to strong criticism of the model-based approach (Hansen, Madow and Tepping, 1983), since such extreme samples can lead to highly biased estimators if the model is misspecified. What this criticism ignores of course is that there is no particular reason why one should not investigate the sensitivity of an optimal model-based design to breakdown of the model assumptions. Such analyses have in fact been a primary focus of model-based strategies for some time, and they typically lead to non-extreme designs which are operationally very similar to many conventional designs.

To illustrate, the model-based strategy defined by the extreme sample and the weights (19) becomes model-biased if the true relationship between Y and X deviates from the strict proportionality relationship defined by (10). If the true relationship between Y and X is in fact described by a polynomial of degree K , say, then the optimal estimator defined by (10) remains model-unbiased provided the sample satisfies a K^{th} order balance condition, i.e. where the sample moments of X of order up to K equal their corresponding population moments (Royall and Herson, 1973). This particular model-robust sample design is certainly not extreme.

It is important to realise that such model-robust strategies are not the 'blanket cures' claimed for probability sampling and design-unbiasedness. They provide a reasonable level

of efficiency over a chosen range of alternative potential models for the distribution of Y given X . In doing so, they lose efficiency at the assumed model (which generates the weights used in \hat{T}_Y). This efficiency loss may be considerable if the range of potential alternative models is wide. In effect, the size of one's insurance premium goes up the greater the number of unpleasant events against which one wants to be protected. At the end of the day, it remains the survey designer's responsibility to carry out a sufficiently careful analysis of whatever data sources are available to ensure that the model underlying the chosen strategy is a good representation of the true distribution of Y given X in the population.

6.3 Robustness By Adapting To The Sample Data

No amount of pre-selection analysis can prepare one for every eventuality. Models that seemed entirely appropriate before the sample data were obtained may suddenly look rather fragile when one has had a chance to actually check out the relationship between Y and X in the sample data. If one adopts a model-based approach this situation is of no great concern. A crucial advantage to adopting this approach is its flexibility. There is no restriction that the model used to develop the sample selection procedures (the 'design' model) should also be used in estimation.

In many cases there are distinct advantages in widening the scope of possible models for Y at the estimation stage of a survey, using the information collected in the sample. A common example of this is post-stratification (Holt and Smith, 1979, Valliant 1993; Nascimento Silva and Skinner 1995). Another example is the widespread use of calibration weighting methods, where original sample weights derived at the time of sample selection (based perhaps on some preliminary model for the population) are modified at the time of estimation so they result in estimates that are unbiased with respect to a final, more complex, 'estimation' model for the population (Deville and Sarndal, 1992). A similar idea underlies the introduction of nonparametric adjustment factors based on a nonparametric smooth of the design model sample residuals (Chambers, Dorfman and Wehrly 1993). These adjustment factors can then be applied to the optimal weights under the design model to obtain final

weights that are much more robust to model misspecification than the original optimal weights. Of course, these modified weights are no longer efficient under the design model, but, as always, one has to pay an efficiency premium for robustness.

As an interesting aside, it can be shown that these model-based nonparametric weights are in some circumstances very similar to the (exactly or approximately) design-unbiased weights derived under the model-assisted approach (Chambers 1996). Consequently, there appears to be scope for these two apparently quite distinct approaches to lead to essentially the same sample inferences. Although further research is needed here, such a confluence may help resolve the debate on which approach is 'best'.

6.4 Is Probability Sampling Essential?

By probability sampling we mean a distribution for \mathbf{S} such that $\Pr(S_i > 0 | \mathbf{X}) > 0$ for all i . This condition is an integral part of any sampling strategy under both the design-based and model-assisted approaches. This is because

- (i) Efficiency is measured either by $\text{Var}(\hat{T}_Y - T_Y | \mathbf{Y}, \mathbf{X})$ or by its expected value under the model, both of which are identically zero if the distribution of \mathbf{S} is degenerate;
- (ii) The requirement that \hat{T}_Y be exactly (or approximately) design-unbiased leads to weights that satisfy (or approximately satisfy) (2). Consequently we require $E(S_i | \mathbf{X}) > 0$ for all i . This is guaranteed by probability sampling;
- (iii) Robustness considerations under both approaches require application of the law of large numbers in order to guarantee that a design-unbiased (or approximately design-unbiased) estimator takes values arbitrarily close to the unknown population total T_Y for large enough populations and samples.

In contrast, probability sampling is not essential under the model-based approach. However, this does not mean that such sampling methods are excluded under this approach. Model-based strategies are typically specified in terms of tight sample constraints (e.g. balance), but no restriction is placed on the actual method used to select the sample. There are good

arguments (e.g. Royall 1976) for using a probability sampling method to actually select the final sample, subject to it satisfying these constraints, in order to avoid the unconscious bias that may creep into the selection process if a nonprobability method of sampling is employed.

In terms of the notation that has been used in this paper, this bias arises because the distributions of the population vectors \mathbf{S} and \mathbf{Y} are no longer independent given \mathbf{X} . In particular, the distribution of \mathbf{S} depends on \mathbf{Y} as well as \mathbf{X} . In such cases the model-based (and model-assisted) results presented in this paper are no longer valid. Alternative results can be derived, provided we can specify the nature of the dependence between \mathbf{S} , \mathbf{Y} and \mathbf{X} . This is typically impossible, or at least very difficult. Consequently, a proponent of the model-based approach will typically favour some form of probability sampling because this guarantees the distributions of \mathbf{S} and \mathbf{Y} are independent given \mathbf{X} .

From a model-based perspective, therefore, the principal argument for using probability sampling is to provide robustness against selection bias effects. However, there is another, more practical, aspect to probability sampling that makes it desirable from a model-based point of view. This is the fact that balanced samples (in the general sense of balance, that is where the sample satisfies conditions which ensure unbiasedness of the proposed estimator within a specified class of possible alternative models for the survey population) are typically easier to achieve provided an appropriate form of randomisation is used.

For example, if the estimator of choice is the simple ratio estimator and the class of alternative models for the population is specified in terms of polynomial regression models of order up to and including K , then a balanced sample is one with all its X -moments up to and including order K equal to the corresponding population moments of X . On expectation over repeated sampling (i.e. in design-expectation) a sample selected with equal inclusion probabilities for all population units will be balanced (Royall and Pfeffermann, 1982; Royall and Cumberland, 1988). Consequently, one way of achieving this type of balance is to take such a probability sample, and use it if it is adequately balanced. Otherwise, we reject it, and select another probability sample. This idea of using probability-based rejective sampling to

screen for adequately balanced samples has been shown to lead more precise inference than the corresponding use of unrestricted randomised sampling (Tam and Chan, 1984; Deville, 1992). More recently, Deville and Tillé (2004) have developed the 'cube' method of selecting a balanced sample with specified sample inclusion probabilities. In general, therefore, there is no tension between robust model-based design and probability sampling. The former provides a criterion that the sample of choice should (at least approximately) satisfy, and the latter provides a mechanism for choosing samples to check against this criterion.

At the end of the day however, one has to ask oneself the question: Is there anything one can do if the underlying population model is such that our estimator, even when computed on a balanced sample, remains biased? That is, the real population model is not a member of the class of models underlying the chosen balance criteria, and so balance does not guarantee unbiasedness with respect to 'reality'. Does the fact that this sample has been selected via some form of randomisation based procedure help? Here it seems that one has no recourse but to design-unbiasedness. That is, the only statements one can make relate to average properties of the estimator over repeated sampling, rather than to the properties of the estimator for the actual sample selected. Since, as we have already pointed out, these average properties may be far from the actual behaviour of the estimator over the chosen sample, the inevitable conclusion one has to draw is that one cannot be protected against everything, and so one has to accept some risk in survey inference. The key property of good sample design is that it minimises this risk (by appropriate choice of model, balance criteria etc.) subject to available resources.

6.5 What Is The Right Way To Measure Precision?

The astute reader will no doubt by now have asked the question: Efficiency of estimation is all very well, but the bottom line in any statistical analysis of sample survey data must be an accurate measure of the precision of that analysis. Where is the discussion on how to measure precision properly? Should one measure the precision of an estimator \hat{T}_y by its design-based

error variance $Var(\hat{T}_Y - T_Y | \mathbf{X}, \mathbf{Y})$ or should one measure it by its model-based error variance $Var(\hat{T}_Y - T_Y | \mathbf{S}, \mathbf{X})$?

Which measure is appropriate depends very much on *what* one means by precision and *when* one is measuring precision. Assuming unbiasedness of \hat{T}_Y , we take precision as being the variance of the estimation error $\hat{T}_Y - T_Y$ with respect to all relevant sources of uncertainty at any particular point in time. Thus, one could argue that since \mathbf{S} is unknown prior to sample selection, the design-based error variance is a measure of our uncertainty about the estimation error *before* the sample is selected. However, it does condition on \mathbf{Y} , which is also unknown before the sample is selected (and only partially known afterwards). Consequently, a better measure of precision before sampling is $Var(\hat{T}_Y - T_Y | \mathbf{X})$.

After the sample is selected, however, and remembering that we are assuming the outcome \mathbf{S} is ancillary (e.g. through probability sampling), it is clear that the appropriate measure of precision is at least the model-based frequentist variance $Var(\hat{T}_Y - T_Y | \mathbf{S}, \mathbf{X})$, or, if one is adopting a Bayesian approach, the posterior variance $Var(\hat{T}_Y - T_Y | \mathbf{S}, \mathbf{X}, \mathbf{Y}_s)$, where \mathbf{Y}_s is the vector of sample Y -values. There is strong empirical evidence (e.g. Royall and Cumberland, 1981) that a variance that does not condition on \mathbf{S} (like the design-based variance) can give a very misleading picture of the precision of \hat{T}_Y once \mathbf{S} is *known*.

The situation gets even more complicated when we consider the problem of *estimating* precision. There are well known methods for estimating the design-based error variance $Var(\hat{T}_Y - T_Y | \mathbf{X}, \mathbf{Y})$ (see Wolter, 2007). Such estimators have model-based properties as well however. Let \hat{V} denote a design-unbiased estimator of $Var(\hat{T}_Y - T_Y | \mathbf{X}, \mathbf{Y})$. That is $E(\hat{V} | \mathbf{X}, \mathbf{Y}) = Var(\hat{T}_Y - T_Y | \mathbf{X}, \mathbf{Y})$. Suppose also that \hat{T}_Y is model-unbiased (as will usually be the case under either the model-assisted or model-based approaches). Then

$$\begin{aligned}
\text{Var}(\hat{T}_Y - T_Y | \mathbf{X}) &= E\left(\text{Var}(\hat{T}_Y - T_Y | \mathbf{X}, \mathbf{Y}) | \mathbf{X}\right) + \text{Var}\left(E(\hat{T}_Y - T_Y | \mathbf{X}, \mathbf{Y}) | \mathbf{X}\right) \\
&= E\left(E(\hat{V} | \mathbf{X}, \mathbf{Y}) | \mathbf{X}\right) + \text{Var}\left(E(\hat{T}_Y - T_Y | \mathbf{X}, \mathbf{Y}) | \mathbf{X}\right) \\
&= E(\hat{V} | \mathbf{X}) + \text{Var}\left(E(\hat{T}_Y - T_Y | \mathbf{X}, \mathbf{Y}) | \mathbf{X}\right) \\
&= E\left(E(\hat{V} | \mathbf{S}, \mathbf{X}) | \mathbf{X}\right) + \text{Var}\left(E(\hat{T}_Y - T_Y | \mathbf{X}, \mathbf{Y}) | \mathbf{X}\right)
\end{aligned}$$

while

$$\begin{aligned}
\text{Var}(\hat{T}_Y - T_Y | \mathbf{X}) &= E\left(\text{Var}(\hat{T}_Y - T_Y | \mathbf{S}, \mathbf{X}) | \mathbf{X}\right) + \text{Var}\left(E(\hat{T}_Y - T_Y | \mathbf{S}, \mathbf{X}) | \mathbf{X}\right) \\
&= E\left(\text{Var}(\hat{T}_Y - T_Y | \mathbf{S}, \mathbf{X}) | \mathbf{X}\right)
\end{aligned}$$

so

$$E\left(E(\hat{V} | \mathbf{S}, \mathbf{X}) - \text{Var}(\hat{T}_Y - T_Y | \mathbf{S}, \mathbf{X}) | \mathbf{X}\right) = -\text{Var}\left(E(\hat{T}_Y - T_Y | \mathbf{X}, \mathbf{Y}) | \mathbf{X}\right)$$

That is, the average model bias of the design unbiased variance estimator \hat{V} is equal to minus the average variance of the design bias of the estimator \hat{T}_Y . In general, therefore, the design unbiased variance estimator \hat{V} will be biased low for the actual post-sample uncertainty of the estimator \hat{T}_Y . One situation where \hat{V} will be a reasonable measure of this uncertainty is where the sample design ensures that the average design bias of \hat{T}_Y varies little between different realisations of Y . This will be the case if \hat{T}_Y is also design-unbiased, or approximately design-unbiased. Sample designs that ensure this condition is satisfied are typically those that lead to balanced samples for \hat{T}_Y . Consequently, design-based variance estimators like \hat{V} are usually 'safe' (in the sense of actually estimating the right thing) in balanced samples. In unbalanced samples, however, they are not to be trusted.

Of course, model-unbiased variance estimators can also be derived, and these will provide correct measures of precision irrespective of the type of sample selected provided the model is correctly specified. However, these variance estimators will no longer be correct if the assumed model is misspecified. Hence robustness of variance estimation is as important as robustness of estimation under the model-based approach.

In a series of papers, Royall and Eberhardt (1975) and Royall and Cumberland (1978, 1981a, 1981b, 1985) have explored a general approach to robustifying standard least squares type model-based variance estimators. Their method assumes correct specification of the conditional mean of Y given X and uses a nonparametric moment estimator (rather than a parametric one) for the leading term in the conditional variance $Var(\hat{T}_Y - T_Y | \mathbf{S}, \mathbf{X})$. Empirical results presented by these authors indicate that the general performance of this robust approach to variance estimation (including confidence interval coverage) is uniformly good provided samples are balanced, or are close to balance. In unbalanced samples, however, presence of bias in the estimator \hat{T}_Y can lead to substantial noncoverage.

At the time of writing there does not appear to be a generally applicable solution (either design-based or model-based) to estimating the precision of a sample survey estimator after the sample has been selected. In particular, accurate variance and confidence interval estimation in unbalanced samples remains an area of current research.

A final point concerns the role of Bayesian ideas in determining a survey strategy. Although these ideas were important in the development of the model-based approach, see Scott and Smith (1969), they do not appear to have been taken up to any significant extent since then. However, due perhaps to the influence of the Bayesian approach in small area area estimation, this may be changing, see Rao (2011).

ACKNOWLEDGEMENTS

The original version of this paper was presented as part of the Workshop on Survey Design and Analysis at the Australian Statistical Congress, Sydney, July 8 - 12 1996. Danny Pfeffermann, Alan Dorfman, Fred Smith, Phil Kokic, Roger Sugden and Chris Skinner all provided comments and suggestions on a subsequently revised version of the paper. Their valuable inputs are gratefully acknowledged, as are those of an anonymous referee. All errors and omissions are the author's sole responsibility, however.
