Factor analysis and validity of a short six-item version of the Desires for Alcohol Questionnaire

Abstract
Reductions in cravings have been associated with improved recovery from alcohol and other drug use problems. Self-report assessments of cravings provide a way of monitoring progress over the course of treatment particularly in residential settings. There is a need to develop brief craving measures suitable for repeat administration. The aim of the study was to assess the reliability and validity of a six-item version of the Desires for Alcohol Questionnaire (DAQ-6). In study 1 exploratory factor analysis involving 710 participants attending residential treatment revealed two factors: 'expectancy of negative reinforcement' and 'strong desires and intentions'. In study 2 confirmatory factor analysis replicated this factor structure in an independent sample of 116 participants. Both studies provided evidence for convergent and discriminant validity of the DAQ-6 when compared to other measures. The DAQ-6 shows promise as a brief self-report measure of cravings but the utility of the separate subscales in treatment contexts requires further research.

1. Introduction

The definition and measurement of alcohol and drug ‘craving’ has been the topic of debate for many decades in research and treatment settings (Drobes & Thomas, 1998; World Health Organisation, 1955). Although craving has been defined in a number of ways, it is commonly understood as a persistent urge or desire to use a substance (American Psychiatric Association, 2000; Kozlowski & Wilkinson, 1987). Theories of addiction have elaborated on this definition by positing that craving is central to substance dependence and relapse, and is generally argued to arise from the positive-reinforcing outcomes of a substance, the negative-reinforcing effects related to substance withdrawal, or a combination of both (e.g. Baker, Piper, Fiore, McCarthy, & Majeskie, 2004; Marlett, 1985; Marlett & Gordon, 1985; Niaura, 2000; Niaura et al., 1988).

In addition to its theoretical importance, the role of craving provides many practical benefits to researchers and clinicians (Drummond Litten, Lowman & Hunt, 2000; Rosenberg, 2009). Some of these benefits include: 1) the ability to make predictions regarding the readiness for treatment discharge and the likelihood of relapse following discharge, 2) recommendations regarding appropriate treatment based on craving profiles, and 3) the development of new treatments aimed at preventing relapse by reducing craving itself, or helping patients to cope more effectively with craving. Given these potential benefits, reliable and valid measures of craving are important in both research and treatment contexts. This is particularly relevant in residential settings because abstinence is often a requirement for patients. Consequently, measures typically used to track progress in outpatient settings, such as quantity or frequency of substance use, are not suitable.
To date, there is still no consensus on an optimal measure of craving (Rosenberg, 2009; Sayette et al., 2000). Traditional measures of craving tended to rely on single-item visual analogue scales to measure the severity of craving (McCormick, Home, & Sheather, 1988). While single-item scales are easy to administer and suitable for repeated use, they are problematic because of questionable reliability and furthermore, they dismiss the multidimensional nature of craving (Anton & Drobes, 1998; McCormick et al., 1988). Interestingly, over the last two decades, researchers have addressed these issues by developing lengthy multi-item questionnaires, but have since reduced the number of items in order to retain the advantages of shorter questionnaires (see Rosenberg, 2009). Examples of questionnaires that have followed this trend include: the Questionnaire of Smoking Urges (QSU; Tiffany & Drobes, 1991), the Obsessive Compulsive Drinking Scale (OCDS; Anton, Moak, & Latham, 1995), and the Desires for Alcohol Questionnaire (DAQ; Clark, 1994) (see Rosenberg, 2009 for a list of multi-item self-report craving questionnaires).

The DAQ, which is the focus of the present study, is one questionnaire that has undergone multiple revisions to determine the optimal number of items and dimensions that capture craving. The original DAQ (Clark, 1994) included 36 items that aimed to assess craving for alcohol. Factor analyses of 302 participants revealed four factors that accounted for 65% of the overall variance. Factors included: “alleviation of negative affect”, “strong desires and intentions”, “mild intentions and positive reinforcement” and “controllability of alcohol consumption once drinking is initiated”. The 36-item was subsequently reduced to a 14-item version by selecting items that loaded highly on each dimension (see Kramer et al., 2010; Love et al., 1998).
Love et al. (1998) administered the 14-item DAQ to 131 participants who were attending treatment for alcohol use. Results revealed four factors that explained 81.5% of the overall variance: “negative reinforcement”, “control over drinking”, “strong desires and intentions to drink”, and “mild desires and intentions to drink”. However, items relating to mild desires loaded alongside those relating to strong desires. This suggests that participants with more severe alcohol problems are less able to distinguish between the intensity of their intentions to drink. Thus, “mild desires” may be a less appropriate factor in this population. Similarly, Kramer et al. (2010) also administered this version of the DAQ to 1500 participants with an alcohol-use disorder (AUD) and 1460 without an AUD. In both subsamples, results revealed a three-factor solution that accounted for over 70% of the overall variance. Items reflected “strong intentions and desire to use”, “negative reinforcement”, and “positive reinforcement and ability to control drinking”. However, they did not reflect mild desires and drinking control was not clearly distinguished from positive reinforcement.

The DAQ has also been used for specific individual substances other than alcohol and shown to have similar craving factor structures. One study developed the Desire for Drug Questionnaire by modifying the 14-item DAQ for heroin-dependent patients (Franken, Hendriks, & van den Brink, 2002). Another study used the original DAQ to develop the Desire of Speed Questionnaire to measure craving for amphetamines and found four factors that were almost identical to the original DAQ factors (James, Davies, & Willner, 2004). However, major limitations of this study were the use of a convenience sample which limits generalisability and, presence of a large number of items that did not fit any of the factors due to high cross loadings on multiple factors.
Closer inspection of the studies reviewed indicates that while the original DAQ proposed four factors that explain craving, subsequent studies have reported two consistent dimensions. These factors are related to strong desires and intentions to use and the reinforcing effects of using the substance. Items related to “mild desires” to use tend to load alongside “strong desires and intentions”. Several studies have also found a two item “control” factor (Franken et al., 2002; James et al., 2004; Love et al., 1998), but one study found that items from this factor loaded on the “positive reinforcement” factor (Kramer et al., 2010). Given that high Cronbach’s alpha has been reported even for the 14-item version (range 0.95 to 0.97) (Love et al., 1998), this indicates some degree of item redundancy. Even relatively short questionnaires can overwhelm participants and increase response errors, particularly if they are administered routinely as part of a larger battery of questionnaires (Marteau & Bekker, 1992; Myers et al., 2003; Taylor & Deane, 2002). Thus, an even briefer version of the DAQ that includes cravings for both alcohol and other drugs would better reflect the mixed background of participants in residential treatment settings and reduce completion times and burden.

1.1. The Present Study

Two studies were conducted to assess the reliability and validity of a brief 6-item version of the DAQ. In Study 1 the exploratory factor analysis was conducted on the 6-item DAQ in a large sample of individuals attending residential drug and alcohol treatment. Convergent validity was assessed by examining the relationship between this version of the DAQ and other measures related to craving that are typically used in SUD contexts. It is expected that this craving measure will correlate positively with measures of symptom distress and negatively with measures of recovery. In Study 2, confirmatory factor analysis (CFA) was conducted on an
independent sample of participants from similar settings in order to determine whether the same factor structure arises. In addition, convergent and divergent validity was assessed.

Study 1

2. Material and Methods

2.1. Participants

Participants were recruited from eight Salvation Army alcohol and drug rehabilitation centres located along the east coast of Australia. The program utilises a 12-Step, faith-based and abstinence-oriented approach to provide up to 10 months of residential treatment to individuals with substance use disorder (SUD). Participants in this study were selected from the cohort of clients who arrived at any of the centres for treatment during the period of June 2008 to July 2010 inclusive. The total number of new admissions and potential participant pool over this time was 1271. Additionally, participants were eligible if they: (i) provided informed consent and (ii) completed the Desire for Alcohol Questionnaire within one week of completing the Addiction Severity Index at treatment entry. Given that craving decreases with abstinence, it was important to ensure that craving was measured as close to treatment entry as possible (e.g. Doherty, Kinnunen, Militello, & Garvey, 1995; McGregor et al., 2005). A total of 712 participants met these criteria, resulting in a 56% participation rate. This sample comprised 579 males (81%) and 133 females (19%). This is consistent with the proportion of beds allocated to males and females across The Salvation Army treatment sites. The average age of participants was 36.75 (SD=10.76). The primary substance of use was alcohol (59.7%) and the average length of problem was 18.38 years (SD=10.99). This was followed by amphetamines (14.4%), cannabis (12.6%), and heroin (5.8%).
2.2. Development of DAQ-6

The 36-item and 14-item DAQ are the two most common versions used to measure craving in research. We did not include all items in the initial design because the research context was such that we needed a brief version of a craving measure to reduce the burden on participants since there were multiple other measures being simultaneously administered as part of routine outcomes assessment in The Salvation Army treatment centres. Thus, the current study is based on secondary analysis of routine outcome data. As discussed, items from the longer versions of the DAQ consistently fall into the dimensions of “strong desire and intention to use” and “negative reinforcement”. Based on such findings, 3 items that loaded highly on each dimension, which were also relevant to residential treatment settings, were chosen. Some studies have included a third “control” factor, but we did not include this factor in part because we based our item selection primarily on the factor analysis of Kramer et al. (2010) who found these control items cross-loaded on another factor. Particular reference was paid to the factor loadings generated from the study by Kramer et al., (2010), where the same items had the highest factor loadings on the two aforementioned factors. These items were worded identically to the original DAQ with the only difference being the replacement of alcohol to include drugs (e.g. drink/use drugs). Participants were prompted to select their drug of preference and then to rate how strongly they agreed or disagreed with each statement on a 7-point Likert Scale ranging from “Strongly disagree” to “Strongly agree”. Examples of items used in this study include: “I want to drink/use drugs so much I could taste it” and “I would feel as if all the bad things in my life disappeared if I drank/used drugs now”.

2.3. Measures
The Drug Taking Confidence Questionnaire (DTCQ) (Sklar, Annis & Turner, 1999) is an 8-item self-report questionnaire that measures a person’s self-efficacy in resisting the urge to drink alcohol or take drugs in specific high risk relapse situations. Participants are asked to rate their confidence on a scale from 0 to 100%, and then scores are averaged to form an overall confidence percentage. Examples of items included asking the participant their confidence to resist the urge to use their primary drug if they felt “angry”, had “trouble sleeping” and wanted to “celebrate”. The construct validity of the DTCQ has been supported by positive correlations with measures of confidence and motivation to quit drinking or using drugs, and negative correlations with a measure of difficulty quitting alcohol and drugs (Sklar & Turner, 1999). Cronbach’s alpha for the DTCQ has been reported as .89 (Sklar & Turner, 1999), and in the current study it was 0.90.

The Addiction Severity Index, fifth edition (ASI-5) (McLellan et al., 1992) is a semi-structured interview used to assess the severity of an individual’s health status in 7 domains: Medical Status, Employment/ Support Status, Alcohol and Drug Use, Legal Status, Family/ Social Relationships and Psychiatric Status. Questions are asked about the extent of these problems in the individual’s lifetime and the past 30 days. The ASI produces a composite score ranging from 0 (no problem) to 1 (severe problem) for each domain. Each composite score indicates the severity of that domain for the past 30 days. The complete ASI was administered, however for the purpose of this study only Alcohol Use and Drug User domains were used.

The Depression Anxiety Stress Scale 21 (DASS-21) (Lovibond & Lovibond, 1995) is a 21 item self-report questionnaire that consists of three scales that measure negative emotional states of depression, anxiety and stress. Items are scored on a 4-point Likert Scale from ‘Did not apply to me at all’ (0) to ‘Applied to me very much or most of the time’ (3) (e.g. ‘I find it hard to...
Desires for Alcohol Questionnaire

wind down’). Cronbach’s alpha for the total score has been reported as .93 (Henry & Crawford, 2005), and in the current study it was 0.96.

The Mental Health Continuum-Short Form (MHC-SF) (Lamers, Westerhof, Bohlmeijer, ten Klooster, & Keves, 2011) measures participants’ feelings of psychological, emotional and social well-being over the past month. Participants rate the frequency of 14 feeling states on a 6-point Likert scale range from ‘Never’ (9) to ‘Every day’ (5). Example of items include ‘Happy’, ‘Interested in life’, and ‘That people are basically good’. Research has confirmed the reliability and validity of the MHC-SF as a measure of positive mental health and wellbeing, with Cronbach’s alpha reported as .89 (Lamers et al., 2011). The Cronbach alpha in the current study was 0.94.

The Recovery Assessment Scale (RAS-24) (Corrigan, Salzer, Ralph, Sangster & Keck, 2004) is a 24 item scale which asks participants to indicate the extent to which they agree with statements about themselves and their lives. It assess: Personal Confidence and Hope, Willingness to ask for Help, Goal and Success Orientation, Reliance on Others and Symptom Coping and No Domination of Symptoms. Items are scored on a 5-point Likert scale ranging from ‘Strongly disagree’ (1) to ‘Strongly agree’ (5), with items such as ‘I have a desire to succeed’. Items are summed to produce a total score, with higher scores indicating greater recovery. The Cronbach alpha for the whole scale in the current study was 0.92.

The Life Engagement Test (LET) (Scheier et al., 2006) is a 6-item scale that measures purpose in life. Items are scored on a 5-point Likert scale ranging from ‘Strongly disagree’ (1) to ‘Strongly agree’ (5), with items such as ‘There is not enough purpose in my life’ (item 1). The reliability of this scale tested across eight samples ranges from .72 to .87 (Scheier et al., 2006). The Cronbach alpha for this study was 0.78.
2.4. Procedure

The intake assessment, which included all the aforementioned measures, was administered during the first admission session conducted at the residential treatment centres. All assessments were conducted by The Salvation Army caseworkers and then all data collected was entered into their electronic file management program. The study protocols were reviewed and approved by the University of Wollongong Human Ethics Committee.

2.5. Statistical analysis

The data collected from the DAQ-6 were analysed using exploratory factor analyses. Only participants that completed questionnaires within seven days of treatment entry were included in the analysis. There were small amounts of missing data and this resulted in 710 cases being retained for the Principal components analysis (PCA). Obtained components of the PCA were subjected to oblique (promax) rotation as previous studies reported intercorrelations among components of craving. The number of factors retained was determined by inspection of scree plots and eigenvalues, as well as interpretability of each component. Additionally, only items with loadings higher or equal to 0.4 were considered part of that component. The reliability of resulting factor scales were checked using Cronbach’s alpha. The data were checked for sampling adequacy and sphericity using the Kaiser-Meyer-Olkin (KMO) and Bartlett tests. The KMO measure in this study was 0.83, which is well above the acceptable limit of .5. Additionally, Barlett’s test of sphericity indicated that correlations between items were sufficiently large and therefore factor analysis is appropriate ($\chi^2 (15) = 2745.56, p < .001$).

Correlations were conducted between the various measures of psychological functioning and drug and alcohol specific variables in order to assess convergent and divergent validity of the DAQ-6. Only a subsample of participants completed the additional measures and analyses for
some variable were restricted to only those who endorsed the specific problem (e.g., ASI Drug 
composite) so sample sizes ranged between 232 and 382 for these pairwise comparisons.

3. Results

3.1. Factor analysis

Factor analysis revealed two factors with eigenvalues of 3.87 and 1.03. Three items 
loaded on the first factor and three items loaded on the second factor. All items on the first factor 
reflected the anticipation of relief from negative states (e.g. “even major problems in my life 
would not bother me if I drank/ used drugs now”). This factor was therefore labelled “expectancy 
of negative reinforcement”. Similarly, all items on the second factor reflected strong desires to 
use alcohol or drugs (e.g. “I would do almost anything to have a drink/ take some drugs right 
now”). This factor was therefore labelled “strong desires and intentions to drink or use drugs”. 
The Pearson correlation between the factors was $r = 0.69$ ($p < 0.01$). Results of the factor 
analysis are summarised in Table 1. Overall these factors accounted for 81.76% of the overall 
variance (64.54% and 17.22% respectively). The scale mean was 2.80 ($SD=1.49$), and the means 
for factors 1 and 2 were 3.01 ($SD=1.89$) and 2.58 ($SD=1.49$) respectively. Cronbach’s alpha of 
0.89 was found for the DAQ-6 in the present study, indicating a good level of internal 
consistency.

[INSERT TABLE 1 HERE]

3.2. Convergent validity of the DAQ-6

Both Spearman’s and Pearson’s correlations were conducted and results were examined 
to see whether results differed in terms of significance, direction and magnitude of relationships. 
Since results were highly consistent across both methods, the decision was made to report 
Pearson’s correlations. Correlations were also conducted separately between the overall DAQ
and each factor with a range of measures that are hypothesized to correlate positively and negatively with craving. As the pattern of results were highly consistent using the overall DAQ and individual factors, correlations using the overall DAQ-6 will be the focus of this study. Results have been reported in Table 2.

[INSERT TABLE 2 HERE]

Consistent with the study’s hypotheses, results indicated that the DAQ-6 correlated positively with measures of alcohol and drug severity (ASI) and psychological distress (DASS-21), and negatively with psychological well-being (MHC-SF), alcohol and drug taking self-efficacy (DTCQ), recovery (RAS) and purpose in life (LET). Measures specific to alcohol and drug taking behaviour (ASI and DTCQ) demonstrated small correlations with craving, whilst those related to psychological distress (DASS-21 and MHC-SF) and other mental health measures (LET and RAS) demonstrated moderate correlations. None of these correlations were so high as to suggest that the DAQ-6 was assessing the same construct as these other measures. These findings suggest that the DAQ-6 has good convergent validity with other measures typically used in SUD contexts.

4. Discussion

The purpose of study 1 was to develop and examine the psychometric properties of a questionnaire suitable for assessing alcohol and drug craving in individuals in residential treatment settings. The DAQ-6 was based on the 36- and 14-item DAQ (Clark, 1994; Love et al., 1998), with two major modifications. First, items were chosen from the two dimensions that have most consistently emerged in prior studies. Second, items were worded such that they were relevant to both alcohol and drug users.
As expected, factor analysis revealed that the 6-items were best described by a two-factor solution. These factors were labelled “expectancy of negative reinforcement” and “strong desires and intentions to drink or use drugs”. The DAQ-6 demonstrated a good level of internal consistency and items accounted for a similar, if not a greater amount of overall variance than reported in previous studies that included more items (Franken et al., 2002; James et al., 2002; Kramer et al., 2010; Love et al., 1998). This is consistent with our observations that while previous studies have reported up to four factors, only two factors have been consistently replicated. Correlations between the DAQ-6 and other measures typically used in SUD contexts were all significant and in the expected direction. Additionally, the pattern of correlations was similar across individual factors, suggesting that while the DAQ-6 captures more than one dimension of craving, these dimensions are related to other variables in very similar ways.

Compared to previous studies which also conducted factor analysis on the DAQ, the only correlation that was smaller than expected in the present study was between craving and alcohol (r = .15) and drug severity (r = .22). One explanation is that both Kramer et al. (2010) and James et al. (2002) used questionnaires that are more focused on substance use symptom severity as opposed to severity based on the amount and frequency of alcohol and drug use. The correlations reported in the two studies were r=0.72 and r=0.41-0.49 respectively. In addition, they compared the DAQ with other self-report questionnaires administered at the same time increasing the likelihood that higher correlations are in part a function of shared method variance. In contrast, our study measured alcohol and drug use severity using the ASI which is an interview based measure. Further, the ASI asked respondents to report alcohol and drug use over the prior 30-days whereas cravings can potentially fluctuate daily or even hourly. Even with
these method and timing differences we still found significant positive correlations between the DAQ-6 and drug and alcohol use measures.

The study upon which we primarily based our item selection only reported two factors. However, we recognise that some studies have reported a third “control” factor. Thus, for researchers and clinicians who are interested in the issue of perceived control, they may wish to include the following two control items: “I could easily limit how much alcohol/ drugs I would drink/ use if I drank/ used drugs now” and “I could easily limit how much alcohol/ drugs I drank/ used right now

5. Study 2

The results from study 1 demonstrated that the DAQ-6 adequately captures two factors of craving and explains a similar proportion of variance compared to the 36-item (Clark, 1996) and 14-item (Love et al., 1998) versions of the DAQ. Study 2 aimed to conduct confirmatory factor analysis on the DAQ-6 in an independent sample of participants, who were also undergoing residential treatment for substance use problems. Additionally, we assessed convergent/concurrent validity with an alternate measure of craving, as well as assessing the relationship of the DAQ-6 with other drug and alcohol measures.

6. Material and Methods

6.1. Participants

Data for the current study was collected from a study examining the effectiveness of a computer based, cognitive behavioral therapy treatment program delivered to participants attending residential treatment for alcohol and drug abuse operated by The Australian Salvation Army (Kelly et al., 2012). Participants who provided informed consent and who satisfied the
diagnostic criteria for an alcohol or other substance dependence disorder were included in the study. Participants completed a baseline assessment prior to any intervention and were then randomly assigned to either a computer delivered substance abuse and depression intervention (treatment condition) or to the active control condition. Only data collected at baseline prior to the intervention was used for the purposes of Study 2. This sample comprised 116 participants. There were 94 males (81%) and 20 females (17.2%), with the average age being 38.19 (SD=10.57) for both genders. The most frequent primary substance of use was alcohol for both genders (51.5%) followed by amphetamines (11.3%), cannabis (10.3%), and heroin (9.3%). The remaining participants were polydrug users. The average length of time participants indicated they had a problem with these substances was 15.78 years (SD=11.42) for both genders.

6.2. Measures

In addition to the DAQ, DTCQ and DASS-21, the following measures were administered:

The Penn Alcohol Craving Scale (PACS) is a five item self-report questionnaire that explores the intensity, frequency and duration of craving throughout the past week (Flannery, Volpicelli, & Pettinati, 1999). In the present study, the scale was modified to include alcohol and other drugs. For example, questions were modified to “During the past week how often have you thought about drinking or using, or about how good drinking alcohol or using drugs would make you feel?”. Cronbach’s alpha for the PACS has been reported as .92 (Flannery et al., 1999).

The Beck Depression Inventory Second Edition (BDI-II) is a 21 item self-report questionnaire that assesses depressive symptoms over the past two weeks (Beck, Steer, & Brown, 1996). Participants were required to respond to a category by picking one statement of a group of statements that best describes the way they feel. For example, participants may respond
to the category “sadness” by choosing a statement ranging from 0 (“I do not feel sad at all”) to 3 (“I am so sad or unhappy that I can’t stand it”). Internal consistency for the BDI-II is high, with coefficients ranging from .91 to .93 (Beck et al., 1996; Dozois, Dobson, & Ahnberg, 1998).

6.3. Statistical analyses

Confirmatory factor analysis with maximum-likelihoods estimation method was conducted using the Analysis of Moment Structures (AMOS) version 17.0 software package. This CFA enabled us to test whether the two-factor model found in study 1 explained the structure of the empirical data collected in the second participant sample. Good model fit can be indicated by a non-significant chi-square statistic and several other fit statistics, including: the Goodness of Fit Index (GFI); the Tucker-Lewis Index (TLI); the Comparative Fit index (CFI); the Normed-Fit Index (NFI); and the Root Mean-Square Error of Approximation (RMSEA). When examining the GFI, TLI, CFI, NFI values less than .90 indicate lack of fit, values between .90 and .95 indicate reasonable fit and values between .95 and 1.00 indicate good fit. Root Mean-Square Error of Approximation values of .05 or lower to indicate good fit and values between .05 and .08 indicate reasonable fit (Byrne, 2001).

7. Results

The DAQ items were positively skewed so square-root and logarithmic transformations were employed to meet the assumption of normality. When using these transformed values in the CFA the \( \chi^2 \) goodness of fit analyses was non-significant, \( \chi^2 (8, N = 106) = 15.17, p = .056 \), indicating that the amount of unexplained variance in the proposed two factor model was not significant. The additional CFA fit statistics also supported an adequate fit of the data to a two factor model (CFI = .986; NFI = .972; TLI = .974; RMSEA = .092; GFI = .957). Similar results were found when the model was run with the non-transformed data, \( \chi^2 (8, N = 106) = 14.46, p \)
Desires for Alcohol Questionnaire 18

= .07 (CFI = .988; NFI = .974; TLI = .978; RMSEA = .088; GFI = .958). Figure 1 presents the results for the CFA with transformed data. Two latent constructs were present: desire and intention and negative reinforcement. The first three items of the DAQ predicted 5% of the variance in the Urges construct while the remaining three items predicted 21% of the variance in the Coping construct. The Pearson correlation between the two factors was $r = 0.69$ (p < .01).

Table 3 provides correlations between the DAQ-6 and other measures. As expected, results indicated that the DAQ-6 correlated positively with measures of alcohol craving (PACS), depression (BDI-II) and psychological distress (DASS-21), and negatively with alcohol and drug refusal self-efficacy (DTCQ). Moderate to large correlations were found between the DAQ-6 and all measures. Importantly, the strongest correlation was found between the DAQ-6 and the PACS indicating good convergent validity with an alternate measure of craving. This was followed by strong correlations between craving and depression, psychological distress, and drug-taking refusal self-efficacy.

8. Discussion

As predicted by Study 1, the CFA demonstrated that the DAQ-6 consists of two factors: “expectancy of negative reinforcement” and “strong desires and intentions to drink or use drugs”. In addition, correlations between the DAQ-6 and other measures typically used in SUD contexts were all significant and in the expected direction, with minor differences between the DAQ-6 individual factors (subscales) and the total score. However, it should be noted that though the CFI, NFI, TLI and GFI values were all indicative of adequate model fit, the RMSEA value was
slightly inflated. RMSEA values of .5 to .8 are generally considered to be indicative of adequate fit (Byrne, 2001). However, researchers should use multiple rather than single fit indices when determining model fit (Chen, Curran, Bollen, Kirby, & Paxton, 2008; Byrne, 2001) and the RMSEA value tends to reject models when small sample sizes and few degrees of freedom are employed (Byrne, 2001; Hu & Bentler, 1999). Thus, we do not believe the RMSEA value is indicative of poor model fit in our analyses.

The DAQ items compliment those provided by the PACS in several respects. The PACS is concerned primarily with quantifying the frequency, intensity, and duration of craving. However, the DAQ items focus more on qualitative experiences of craving, that is, the thoughts and feelings associated with craving. For example, in the two factor model, items are related to the reinforcing effects of using the substance and also the strong desire and intention to use.

We believe that the more qualitative perceptions tapped by items on the DAQ may be of additional utility in assessing cravings in residential settings. Although, it is unclear whether craving differs between residential and outpatient treatment centres, researchers have postulated that abstinent individuals in residential treatments may experience craving differently (Rohsenhow & Monti, 1999). On the one hand, craving may be heightened because individuals are involuntarily prevented from substance use. On the other hand, craving may be infrequent and contained because individuals are not exposed to drug related stimuli that would normally provoke craving. Furthermore, there is evidence that drug availability influences the magnitude of craving, such that craving is enhanced when the individual believes they have immediate access to the desired drug (Carter & Tiffany, 2001).

The frequency and intensity type items of the PACS may be more responsive to contexts where specific exposure to drugs and alcohol are more frequently present. The qualitative
experience of cravings captured in the DAQ may be more related to perceptions of craving and appear less dependent on exposure to cues. At present this is speculative, but could be tested by comparing PACS and DAQ scores before and after exposure to situations that might cue cravings (e.g., walking past a bar).

In the current samples the two subscales of the DAQ-6 had similar correlations with other measures. The Negative Reinforcement and Desire and Intention subscales have potential clinical utility in treatment contexts. For example, the Negative Reinforcement subscale captures the extent to which respondents feel that drinking or drug use would provide relief from negative affect or life problems. Drinking to relieve distressing mood states has been repeatedly found (e.g., Holahan, Moos, Holahan Cronkite & Randall, 2001; McDonald & Meyer, 2011) and negative affect and craving cued relapse accounted for 68% of the reasons for relapse in the 12 months since alcohol treatment initiation on one study (Zywiak, Westerbert, Connors & Maisto, 2003). All of the 85 clients who relapsed were at greatest risk within the first 2 months of treatment and the highest reasons for relapse in this window of time were negative affect followed by craving cued relapse (Zywiak et al., 2003). The negative reinforcement subscale has the potential to identify those individuals who may be more at risk of relapse due to craving focused on relief of negative emotional states. This provides the opportunities for treatment staff to not only identify risk of relapse but to adjust treatment content that might target alternative coping strategies to manage these negative emotional states or problems. The Desire and Intention subscale of the DAQ-6 reflects strong overwhelming wishes to drink or use drugs and that may be more akin to the craving-cued reason for relapse. It has been suggested that anti-craving medications (e.g., naltrexone) may be particularly important to consider under such circumstances (Zywiak et al., 2003). To help determine the clinical utility of the two factors in
the DAQ-6 it would be useful to administer the DAQ-6 regularly through residential treatment and then follow-up participants after discharge to monitor subsequent relapse. In addition, a measure of the reasons for drinking/drug use could be administered to clarify whether the DAQ-6 subscales were able to also predict reasons for relapse.

9. Limitations

This study has two main limitations. Firstly, we recognize that the design of the study could have been strengthened if all items from longer versions of the DAQ were initially included before conducting exploratory factor analysis, and subsequent confirmatory factor analysis to obtain the resulting factor solution. Secondly, the measures we included to conduct concurrent validity were selected from a battery of routine assessments administered at Salvation Army alcohol and drug rehabilitation centres. These assessments were not necessarily specific measures that support the two factor structure of the DAQ; thus, further research is needed with more specific measures to further validate the two factors found in the 6-item version of the DAQ.

10. Conclusion

Overall, findings from the present study provide preliminary evidence that the DAQ-6 is a reliable and valid measure of craving in SUD populations. Given that the DAQ-6 includes substantially fewer items than both the 36- and 14-item versions, it provides a promising alternative in research and treatment contexts where questionnaires are often repeatedly administered and part of a larger battery of questionnaires. The brief nature of the measure combined with the capacity to tap into multiple components of craving provides a number of advantages over longer versions or brief measures that tap a single construct (e.g., PAC). A number of models of recovery from substance abuse theorise that successful management of
cravings provides an important role in recovery (e.g. Niaura, 2000; Niaura et al., 1988; Witkiewitz & Marlatt, 2007). The ability to take multiple measures of craving over time with minimal demand on participants offers the opportunity to monitor cravings during the treatment process to gauge progress. It is likely that this information will be useful to inform individual client care although further research is needed to assess the sensitivity of the cravings measure to changes over the course of treatment and their relationship with longer-term outcomes.
