Drug misuse should always be considered in young people with impaired consciousness

Abstract
We agree with Ikeda et al that the absence of systolic hypertension may provide some discriminatory power towards exclusion of brain lesions, be they ischaemic, haemorrhagic, or space occupying in nature. However, we disagree with them that neurological examination of patients with impaired consciousness is often a waste of time and resources and can delay diagnosis.

Indiscriminate investigations have adverse effects

Editor—The application of evidence based medicine is leading to better treatments by thorough evaluation of treatments based on analyses of risks and benefits. These balance the beneficial clinical gains against the adverse pharmacological and medical effects, using information derived from randomised controlled trials and cost effectiveness studies. In contrast, no such critical approach has been taken for diagnostic tests nor have the consequences and adverse effects of inappropriate investigations been explored. The debate around diagnostic tests has centred largely on minimising the unit costs of the delivery of tests in the light of the enormous increase in the demand for investigations without an obvious and proportionate improvement in health status.1

The case report by Krishnan et al highlights an adverse effect of an inappropriate investigation in a woman with hypothyroid induced ascites.2 The published literature is clear that ascites, and any serous effusion of any aetiology, is associated with raised CA125 concentration.3 Yet despite this evidence, the interpretation of a false positive result triggered a number of adverse effects and consequences—namely, a clinical consultation by an oncologist, computed tomography of the abdomen, diagnostic laparoscopy, mammography, and oral gastroduodenoscopy. These inappropriate secondary investigations carry considerable physical, emotional, and financial cost.

What can we do to improve the appropriate use of laboratory and radiological investigations? Previous attempts at educating clinical staff have shown only short lived improvements.4 We need better solutions because there is a vicious amplification cycle in which increases in investigations are mirrored by increases in operative procedures,5 justified on the basis of the investigations which themselves generate investigations. This increase in test volume increases the probability of error and harm to patients. The discipline of evidence based diagnostics may not exist because we do not know what questions to ask in relation to investigation strategies or because there are no hard endpoints (such as death or cure) to judge success as in pharmacological studies. That should not be an excuse to ignore a significant problem. Where the definition of a disease is made by laboratory and radiological investigations, it is mandatory that the error rate and interferences in the tests are recognised.

Simple presentation of test accuracy may lead to inflated disease probabilities

Editor—We found that conveying information on the accuracy of tests in non-technical language improved doctors’ ability to estimate disease probabilities accurately.6 We investigated whether doctors might misuse such non-technical presentation when considering the probability of endometrial cancer in a patient with positive results on transvaginal ultrasonography.

We presented 263 general practitioners in Switzerland with a pre-test probability of 10%, information that the patient was aged 65, and a positive transvaginal ultrasound result. Ninety two general practitioners (group 1) received no information on the test’s accuracy; 92 (group 2) were told that the sensitivity of the test was 80% and specificity 60%; and 79 (group 3) were told that a positive result is obtained twice as frequently in women with endometrial cancer as in those without the disease, reflecting a likelihood ratio of 2. The last two statements are numerically equivalent since the likelihood ratio equals sensitivity/(1—specificity).

The table shows that the degree of overestimation of diagnostic accuracy varied with the presentational format. As we found previously,7 almost half of the doctors did not change their probability estimates after they were provided with the patient’s age.

We also found that the non-technical format resulted in 25 of the 79 general practitioners in group 3 (52% (95% confidence interval 22% to 43%)) multiplying their pre-test probability by exactly 2. This is theoretically incorrect since, for example, a likelihood ratio of 2 changes a pre-test probability of 40% to 57% only, not to 80%, which requires a likelihood ratio of 6. Unfortunately, in our study, this mistake helped those respondents who did not change their pre-test probability after being given the patient’s age to get close to the correct value.

*Kruskal-Wallis test.

Formulas to convert pre-test probability (P1) into post-test probability (P2):

Pre-test odds—likelihood ratio—post-test odds, where pre-test odds = P1/(1−P1) and P2—post-test odds/(1+post-test odds).

Group 1 received no information on the test’s accuracy; group 2 were told that the sensitivity of the test was 80% and specificity 60%; group 3 were told that a positive result is obtained twice as frequently in women with endometrial cancer as those without the disease.

Actual likelihood ratio associated with the test result was 2.25.
Effect of computerised evidence based guidelines

Computer support is complex intervention

Entorr—Eccles et al’s rigorous approach to the evaluation of a computerised decision support system for the management of angina and asthma accounted for many of the flaws in previous trials of computer support.1 They were no doubt disappointed that no effect was seen, probably due to low usage of the system.

Although not discussed in the paper, a possible explanation for this is that, given the comparatively high use of computers required for inclusion in the trial, the practices already used simpler computerised templates to promote collection of process of care data. Practitioners may therefore have perceived little further to be gained by incorporating computer decision support into their clinical practice.

Such interventions will probably require subspecialisation within a general practice, as proposed in the new general practitioner contract.1

Providing focused training to key people in a practice and supporting subspecialisation through computer decision support may be a more appropriate approach to chronic disease management in primary care: Furthermore, as suggesting that the British army should give up its rifles because of their current technical problems.

Prodigy contract (Department of Health).

It is good to be honest and say that systems were not used

Entorr—The paper by Eccles et al possesses academic integrity, which is widely lacking in computing research.1

I was the main researcher for the first two phases of the Prodigy project and believe that this project has much to teach the Prodigy team. One of the first detailed reports I wrote on Prodigy in 1998 indicated that Prodigy was actually used very little, about seven times a week, and most of the time (88%) users requested to bypass the system (www.robinhi2.freeserve.co.uk/virtualclassroom/chap13/report1.pdf). I am very heartened to see that this type of information is being disseminated rather than suppressed, as was the case with the report I produced.

Opportunity was missed

Entorr—Eccles et al performed a methodologically sound study of a poorly developed intervention.1 They define a computerised support system as a system that compares patients’ characteristics with a knowledge base and then guides a health provider by offering patient specific and situation specific advice.1

The intervention developed and tested in their study does not seem to meet these...
criteria. It did not depend on patient specific information but entry of a more general Read code. It did not contain a reminder to initiate review of patient care or arrange follow up. How far treatment recommendations depended on the patient’s individual clinical review rather than issuing more generic recommendations for treatment is also unclear.

The Prodigy system, the intervention around which this study was based, is an electronic version of a paper guideline that is triggered by entry of a prespecified Read code. By making this the only way in which to enter the computerised guideline the investigators ensured a low level of use during the study. General practitioners are unlikely to continue to enter the same Read code at every consultation as it would mean that each participating patient would have multiple duplicate entries of the same Read code in their electronic record.

By excluding any sort of reminder function in their system,1 the investigators have not accounted for a barrier in managing chronic diseases—recognition, recall, and regular review of patients. Analysis of factors that operate in managing angina and asthma should have uncovered such barriers before the start of this study.2

Other details about the use of the computerised guideline require clarification. What is the definitive number of patients randomised and followed up in each practice for each intervention? What is the number (percentage) of patients in whom the computer guideline went past the first screen? What is the number (percentage) for whom a complete record entry was made? The authors make no comment on the differential use of the electronic guidelines by the two computer suppliers.

This study reinforces the fact that passive diffusion of guidelines, in electronic or paper format, is an ineffective way to implement best practice.1 Paying insufficient attention to how a computer interface operates has produced low levels of usage and made the evaluation less useful than it might have been.2 Future studies should take into account the different functions of computer based clinical decision support systems,3 rather than simply generate suggestions to alter prescribing practice.4

Effect may be function of incentive

Enrion—in their paper Grinshwah et al showed that even very small incentives available does not result in people using them.1 Analogously, Eccles et al showed that having a decision support system available does not lead to people using it. Benson advocated incentives are needed before healthcare workers start using computers.5 In contrast to Eccles et al, van Wijk et al showed effects from a guideline decision support system. They say their general practitioners in these studies had used the tool, whereas such incentives were missing in Eccles et al’s design. We believe that authors of papers describing an evaluation of a decision support system should in the future explicitly discuss incentives for and barriers to using these systems.

Authors’ reply

Enrion—We agree that complex interventions should ideally be developed through an iterative process. Exceptions to this include evaluating a preformed intervention that would not otherwise be rigorously evaluated. This was the case at the outset of our study, although our intervention was heavily on the iterative development of Prodigy software. We conducted an integrated process evaluation to understand the results better. This will appear in the BMJ shortly.

The NHS has invested huge amounts of money in information technology, sometimes for little or no benefit. The evaluation of information technology is complex and multifaceted, but a computerised decision support system can be evaluated as a health technology.6–8 An iterative evaluation may be an important element of software development, until someone comes up with better methods of producing unbiased estimates of effectiveness and efficiency we maintain that all health technologies should be considered evaluative in randomised controlled trials.

Important methodological issues exist about the timing and duration of such evaluations, and we agree with Purves that they should be performed on stable systems. Given the cyclical nature of software development and the self belief and enthusiasm of developers, such points must be pre-specified and enacted to avoid self perpetuating iterative cycles of development with the constant promise of jam tomorrow.

Our description of the system that we evaluated is accurate, and none of the authors dissented from it up to the point of publication.

Data were collected from November 1997 to September 2000, with the intervention running during the last 15 months of this time period. The trial was paused for six months while the software team worked on improvements. The rates of presentation of patients we reported equated to opportunities for the system to be used between twice a day and every other day. Furthermore, the researchers had decided that the start of the intervention period, Prodigy software had become available and was delivered to trial practices alongside the study software. Our feedback from practices indicated that at least some asked for the Prodigy software to be turned off. This echoes Beaumont’s letter and implies that increasing the number of guidelines offered may not be the remedy that Purves suggests.

Two correspondents identified the importance of the issue of training. Contrary to Purves’s letter, two people from each practice were invited to a one day training session and the software was installed within 10 weeks by the computer supplier of two thirds of the trial practices. For the second supplier this interval was almost double, owing to unforeseeable commercial considerations in the company. We acknowledged the importance of training while suggesting that what happened was representative of the real world of primary care. We still believe this to be true but support Emery’s and Purves’s call for better training in service settings.

Fahey et al say that the low levels of use of the system were partly due to requiring the entry of a single Read code and lack of responsiveness to patient specific information. Initially the system could be triggered automatically by a range of specified Read codes in the patient record. It could also be triggered by a clinician entering Read codes selected by the practice and was therefore not a passive method of dissemination. But this was changed in response to requests from the study practices. The automatic triggering was removed and a customisable Read code entry method was used for the final eight months of the intervention. Thus the system did rely on patient specific information.

Emery said that we may have had a ceiling effect due to practices currently using computerised templates. This seems unlikely because only 26% of practices already had

computerised guidelines or protocols for angina and 46% for asthma.

Within Emery’s suggestion of specified models of care we see the risk that clinicians and patients in primary care will be constrained to consult in ways that computers can cope with, rather than addressing the challenge of the integration of computers into patient centered consultations.

Novartis was not in breach of code for “inventing” disease

Entror—Ferriman’s new item is incorrect on at least two counts.

Firstly, it is not true to state that the authority had imposed no penalty on the company for issuing misleading literature. Novartis, like all companies ruled in breach of the code in previous cases, had been notified of Dr Robert Flowerdew’s concerns and well in advance of Novartis being required by the authority to withdraw all relevant material. For times a year the authority publishes detailed case reports in the Code of Practice Review. The review is widely circulated by the authority and is available on request. There is also some secondary publication of the reports. Publicity is seen as a major sanction. I anticipate that the report on this case will be published in this month’s edition of the Code of Practice Review.

Secondly, the impression from the headling to the article, as above, is misleading. Novartis was not ruled in breach of the code for inventing a disease. Novartis was ruled in breach of the code for giving a misleading impression of the effect of Starlix on cardiovascular mortality and risk as detailed in the main body of the article.

Assortative mating may explain spouses’ risk of same disease

Entror—Hippisley-Cox et al observed significant similarities for disease between spouses in a large sample of 8386 couples recruited through general practice.1 They think that shared environmental factors may cause these similarities but reject assortative mating as an explanation.

In a sample from the Netherlands twin register we could not replicate their spouse similarities for asthma, depression, diabetes, and cardiovascular disease, possibly because of our smaller sample size of 2122 spouse pairs.2 When we examined health behaviour in a larger sample we found good associations between spouses for smoking, alcohol problems, and exercise behaviour, even after controlling for age and body mass index of both spouses.

The duration of the relationship influenced these associations between spouses (r, 0.386, r, 0.334, r, 0.387 for < 5 years, > 5 years, and > 15 years, respectively), possibly owing to convergence of phenotypes of the spouses or to a higher divorce rate in dissimilar pairs.3 Significant correlations between spouses were also found for intelligence, a personality trait associated with increased risk behaviour, but these correlations were unaffected by the duration of the relationship (r, 0.386, r, 0.334, r, 0.373 for < 5 years, > 5 years, and > 15 years, respectively).

These results show that different mechanisms underlie similarities between spouses for health behaviour, social factors, and personality traits. The fact that similarities between spouses were found for this wide range of variables indicates, however, that assortative mating should not be harshly dismissed as a cause for spouse similarities in disease.

Any association between spouses does not exclude genetic effects. Hippisley-Cox et al assume that because spouses are unrelated, genes do not influence the association. But the similarity of spouses may be an example of a particular genotype-environment correlation which occurs when a particular genotype is associated with the selection or creation of a particular environmental circumstance.

Drug misuse should always be considered in young people with impaired consciousness

Entror—We agree with Ikeda et al that the absence of systolic hypertension may provide some discriminatory power towards exclusion of brain lesions, being either ischaemic, haemorrhagic, or space occupying in nature.1 However, we disagree with them that neurological examination of patients with impaired consciousness is often a waste of time and resources and can delay diagnosis.

Although hypertension may be an important potential marker, a careful neurological examination of the papillary response, reflexes, and fundoscopy is an important part of the assessment of any patient with impaired consciousness.2

Furthermore, we would like to raise concern over the idea that impaired consciousness in conjunction with systolic hypertension implies that a brain lesion is present. This may be true for older people (the mean age in the Ikeda study was 65 years), but in our experience, impaired consciousness with systolic hypertension in younger people (< 30 years) implies ingestion of sympathomimetic drugs—for example, ecstasy, amphetamine, cocaine.3

Hypertension secondary to ingestion of sympathomimetic drugs requires urgent correction (usually with intravenous nitrates) to prevent secondary complications such as intracerebral haemorrhage, renal failure,
and myocardial ischaemia; if, as is said by Ikeda et al, the hypertension and impaired consciousness are assumed to be related to a brain lesion, the delays in obtaining imaging investigations could lead to delays in instituting potentially life saving treatment.

The possibility of illicit drug ingestion should be considered in any young, hypertensive patient presenting to an emergency department with reduced consciousness, so that appropriate management can be started without delay.

Unit of analysis errors should be clarified in meta-analyses

Ennor—Weingarten et al present a comprehensive study in what is a complex area of research. We were, however, unclear whether any of the included primary studies had unit of analysis errors and how the authors dealt with such studies in their meta-analysis.

Unit of analysis errors occur in cluster randomised trials when individual patients’ data are analysed as if there was no clustering in the provision of intervention, or units randomised to the intervention groups (patients’ data are analysed as independent observations). Standard statistical methods that do not account for cluster effects in cluster randomised trial data result in the overestimation of the significance of an intervention (artificially extreme P values and overly narrow confidence intervals). Correspondingly, the inclusion of studies with unit of analysis errors in a meta-analysis will give greater weight to the results of such studies.

The table of included studies reported by Weingarten et al indicated that the unit of analysis differed from the unit of randomisation in 22 cluster randomised trials, but it was not clear from the report how often unit of analysis errors occurred in these studies or how the authors dealt with studies with such errors in the meta-analysis. Methods exist for re-analysing studies with such errors.

We recently completed a systematic review of guideline dissemination and implementation strategies; 51 out of 110 cluster randomised trials had unit of analysis errors, and reanalysis was possible in only one study. Poor reporting of cluster randomised trials has led to a proposed extension to the CONSORT statement, which is currently under discussion. Systematic reviews of studies with unit of analysis errors should clearly state how they handled such studies in a review.

GPs can separate oncological wheat from chaff

Ennor—Summerton’s editorial on the importance of identifying symptoms potentially indicating an underlying cancer in primary care calls for research based theory. Only community based studies will help general practitioners to decide on the importance of a symptom or physical sign reported by their patients as hospital series are unrepresentative.

Although selection bias is part of the problem, it may be comparatively minor as most patients with cancer are treated in secondary care, even though their disease is diagnosed in primary care. Perhaps more important is bias from the development of symptoms in the time from the first symptom appearing to presentation in primary care and finally hospital.

General practitioners are already quite successful in sifting out the wheat from the chaff (although the comparative rarity of cancer in primary care indicates that a better farming analogy would be finding a needle in the haystack). For example, an estimated positive predictive value for colorectal cancer of rectal bleeding in the community is 0.1%.2,3 Once it is reported to the doctor this rises to 2-3%,4 and in patients referred for investigation it is 5.2%.5

Look before you flush

Ennor—Moayyedi and Ford described recent advances in gastroenterology. The national programme for early detection of colon cancer uses the following statement to raise public awareness for early detection of rectal bleeding: “Look at it before you flush it.” It is really helpful to make people aware of looking for early signs of colon cancer, but I have noticed some important things that might hinder this national programme.

The lavatory disinfectants now sold in supermarkets are mostly blue in colour and change water blue, which makes looking for any blood quite difficult. I suggest that we stop selling colouring agents and replace them by colourless ones or even use reagents that turn a certain colour in the presence of minor blood amounts. Can we?
