Single-crystal growth and anisotropic magnetic properties of nonstoichiometric three-layer sodium cobalt oxides

Abstract
Large single crystals of $\alpha$-Na$_x$CoO$_2$ ($x=0.91$, 0.92, and 0.93) have been successfully fabricated by using the traveling solvent floating zone method. Details on the crystal growth are discussed. The crystal structures were characterized using powder x-ray diffraction and Rietveld refinement. The magnetic susceptibility measurements show that the magnetic properties depend strongly on $x$. The compound was found to be antiferromagnetic at $T_N \approx 20$ K for $x=0.91$ and $x=0.92$, and paramagnetic for $x=0.93$. The in-plane and out-of-plane anisotropies were observed for the $x=0.91$ crystals. In addition, the derived anisotropic g-factor ratios ($g_{ab}/g_c$) from the anisotropic susceptibility along $H||ab$ and $H||c$ decreased significantly as the sodium composition increased from $x=0.91$ to $x=0.93$.

Large single crystals of \( \alpha\)-Na\(_x\)CoO\(_2\) \((x=0.91, 0.92, \) and 0.93) have been successfully fabricated by using the traveling solvent floating zone method. Details on the crystal growth are discussed. The crystal structures were characterized using powder x-ray diffraction and Rietveld refinement. The magnetic susceptibility measurements show that the magnetic properties depend strongly on \( x \). The compound was found to be antiferromagnetic at \( T_N \approx 20 \) K for \( x=0.91 \) and \( x=0.92 \), and paramagnetic for \( x=0.93 \). The in-plane and out-of-plane anisotropies were observed for the \( x=0.91 \) crystals. In addition, the derived anisotropic \( g \)-factor ratios \((g_{\text{ab}}/g_c)\) from the anisotropic susceptibility along \( H_{\parallel ab} \) and \( H_{\parallel c} \) decreased significantly as the sodium composition increased from \( x=0.91 \) to \( x=0.93 \).

I. INTRODUCTION

Since the discovery of simultaneous surprisingly high thermoelectric power and low resistivity in Na\(_x\)CoO\(_2\) \((x=1)\),1,2 and in particular, the discovery of superconductivity at temperatures below 5 K in Na\(_{0.35}\)CoO\(_2\).1.3H\(_2\)O, which is formed by the deintercalation of Na from double layer \( \gamma\)-Na\(_x\)CoO\(_2\) followed by a full hydration process,3 these materials have attracted considerable interest. Early investigations on the sodium-cobalt-oxygen system have revealed that crystals with the formula Na\(_x\)CoO\(_2\) \((x=1)\) are bronze type phases, consisting of sheets of octahedra \((\text{CoO}_2)_6\) between which are inserted sodium ions.4 The unit cell of \( \gamma\)-Na\(_x\)CoO\(_2\) has a \( P2_1 \) structure (prismatic, two layer), i.e., with two sheets of edge shared CoO\(_2\) in its unit cell, which are rotated by 60° with respect to each other. The sodium ions, on two crystallographically distinct sites, are trigonal prismatic \((P)\) in coordination to the oxygen atoms. \( \alpha\)-Na\(_x\)CoO\(_2\) has an \( O3 \) structure (octahedral, three layer), i.e., has three sheets of edge shared CoO\(_2\) per unit cell, displaced laterally from each other. The sodium ions are located only on one crystallographic site in an octahedron \((O)\), with coordination to the oxygen atoms.

The transport and magnetic properties of two-layer Na\(_x\)CoO\(_2\) are strongly dependent on the Na content. It has been found that as \( x \) increases from 0.3, the ground state of these compounds goes from a paramagnetic metal through a charge ordered insulator \((x=0.5)\) to a “Curie-Weiss metal” \((x=0.70)\), and finally, to a weak-moment magnetically ordered state \((x>0.75)\).5 Muon spin rotation and NMR measurements have identified the stoichiometric three-layer Na\(_x\)CoO\(_2\) phase to be a nonmagnetic insulator.6,7

No superconductivity has been found in a new series of sodium cobalt oxyhydrates obtained from the parent compound \( \beta\)-Na\(_{0.9}\)CoO\(_2\),8 whereas the sodium cobalt oxyhydrates formed from \( \alpha\)-Na\(_{0.9}\)CoO\(_2\) show superconducting transitions at 4.3–4.6 K.9,10 Both parent materials have three CoO\(_2\) layers per unit cell, in contrast to the first superconductor, Na\(_{0.9}\)CoO\(_2\).1.3H\(_2\)O, which was obtained from a parent \( \gamma\)-Na\(_{0.9}\)CoO\(_2\) containing only two CoO\(_2\) layers per unit cell. This indicates that the geometrical shape of the site for the Na ions and the number of CoO\(_2\) sheets play an important role in the resultant electronic and magnetic properties.

Single crystals are very desirable for experiments that require large volumes or areas of samples, such as neutron diffraction and anisotropic property measurements. Data obtained from the single-crystal samples will shed light on the electronic and structural properties of this new type of superconductor. There has been much research on this family of materials. Single-crystalline whiskers with \( x=0.5 \) have been grown by an unconventional method from potassium-containing compositions. The maximum size of the whiskers is 1.6 mm in length, 15–40 \( \mu \)m in width, and 1.5–4.0 \( \mu \)m in thickness.11 Using NaCl as a flux, platelike single crystals of NaCoO\(_2\) and NaCoO\(_2\) have been prepared with typical sizes of 1.5 \( \times \) 1.5 \( \times \) 0.03 mm\(^3\) and 0.5 \( \times \) 0.5 \( \times \) 0.02 mm\(^3\), respectively.1,12–14 Compared to these methods, the traveling solvent floating zone \((\text{TSFZ})\) method is just as suitable for such single-crystal growth. In principle, crystal growth can be performed continuously at one point on the temperature-composition phase diagram. Chou et al. succeeded in growing large single crystals of two-layer Na\(_x\)CoO\(_2\) from a feed rod with \( x=0.75 \) using an optical floating zone furnace under oxygen atmosphere.15 Single crystals of Na\(_{0.9}\)CoO\(_2\) with nominal Na content from 0.50 to 1.00 have also been grown successfully using the TSFZ method.16–18 In this contribution, we present a detailed study on the crystal growth of large and high quality three-layer Na\(_x\)CoO\(_2\) \((x=0.91, 0.92, \) and 0.93) single crystals by the floating zone method and demonstrate their structural behavior and anisotropic magnetic properties.

II. EXPERIMENT

The feed rods for the crystal growth were prepared by the conventional solid-state method. Powders of Na\(_2\)O\(_2\) \((97\%)\) and CoO\(_x\) \((99.998\%)\) were mixed in the molar ratios Na:Co\(_{0.9}\)=1.00:1.00, 1.05:1.00, and 1.10:1.00 in an argon filled glovebox. The temperature was slowly \((150 \degree C/h)\) increased to 850 \( \degree \)C, held constant for 24 h, and, finally,
slowly cooled down to room temperature in flowing oxygen. The polycrystalline powders were reground and formed into cylindrical rods 7 mm in diameter and 80 mm in length in an argon filled glovebox. The rods were hydrostatically pressed under a pressure of ~70 MPa and then sintered at 900 °C for 24 h in flowing oxygen. After sintering, a 20 mm long rod was cut to serve as the first seed for crystal growth.

The crystal growth was performed in an infrared radiation furnace equipped with four 300 W halogen lamps. Prior to the crystal growth, a high density feed rod (~90% of the crystal density) was obtained by premelting the rod at the rapid rate of 25 mm/h in flowing oxygen. A short polycrystalline premelted feed rod (~20 mm in length) was used as the seed rod in the crystal growth. Trials were made in which crystals were grown in different atmospheric compositions and pressures as follows: flowing oxygen, flowing argon, and low oxygen pressure (2 atm). The crystal growth speed also varied between 1 and 5 mm/h accompanied by a counter-rotation of the feed and seed rods at 30 rpm to ensure efficient mixing of the liquid and uniform temperature distribution in the molten zone.

Crystal wafers were cut perpendicular to the growth direction and polished to a mirror finish to allow us to examine them for the existence of macroscopic defects such as cracks and twins, grain boundaries, and inclusions under a polarized microscope. Composition analysis of the as-grown crystals was obtained from induction-coupled plasma atomic emission spectroscopy (ICP-AES). A Mo Ka x-ray source was used for powder x-ray diffraction (XRD) measurements to check the phase purity and the crystal structure.

Single-crystal XRD was carried out on mechanically cleaved faces of the crystals along the growth direction to examine the crystalline quality and orientation of the crystal growth. The measurements were conducted in a θ-2θ scan mode in the 2θ range of 10°–120° for single-crystal measurements. Cu Kα radiation was used as x-ray source.

The magnetic susceptibility measurements were carried out using a superconducting quantum interference device magnetometer (Quantum Design, model MPMS 7.0) over the large temperature range of 2–350 K. Magnetic fields were perpendicular and parallel to the c axis for cleaved as-grown crystals.

III. RESULTS AND DISCUSSION

A. Crystal growth

When preparing the polycrystalline NaCoO2 by the solid-state method, sintering the feed rods, premelting the feed rods, and growing the crystals at high temperatures, the sodium loss caused by high Na2O vapor pressure should be considered. Therefore, ceramic powders were synthesized using additional Na2O for compensation. Sintered powders were observed by XRD to consist of a main phase of α-NaCoO2 with little Co3O4 impurity mixture, due to the slow reaction in the core of the rod compared to the outside area; this is what normally happens in this series of compounds. Crystals grown using the impure feed rod did not contain any impurities since Na has a large solubility range in the α phase in this system, and the Na loss is corrected by homogeneous mixing in the following molten process.

Crystals grown under different conditions follow the aforementioned procedures. The quality of the premelted feed rods is one of the critical conditions of the TSFZ technique, because during the crystal growth the molten zone is sustained by the feed rod through surface tension. A straight, long, and equal-diameter feed rod is required to stabilize the molten zone over a long growth period. We found that it was very difficult to stabilize the molten zone during the atmospheric flow, due to the evaporation of Na, which can be observed as white Na2O deposited on the inner wall of the quartz tube, with the molten zone collapse being the result of the composition change. Application of low-pressure oxygen (2 atm) during growth was found to greatly reduce the Na evaporation. Under these conditions, zone travel rates of 1.0, 2.0, 3.0, and 5.0 mm/h were employed. It was found that the zone travel rates in this range have no detectable influence on the crystal quality. However, we observed that the slower rate stabilized the molten zone. Considering the evaporation of Na ions during the growth, much slower rates were not applied.

Figure 1(a) presents a typical α-NaCoO2 boule, which was grown at the moderate rate of 2 mm/h under an oxygen pressure of 2 atm in an attempt to reduce the volatilization of Na and obtain large crystals. The boule was black with a metallic luster, and was 5 mm in diameter and 37 mm in length. The arrow indicates the crystal growth direction. Due to the layer growth mechanism, the crystal grains were found to grow preferentially along the crystallographic ab plane, parallel to the rod axis. It was found that the cleaved surface of the as-grown crystal was shiny, but unstable under atmospheric conditions, in contrast to γ-phase Na2CoO4 crystal. The cleaved surface became dull just 20 min after cleavage due to its reaction with moisture and CO2 in the air. The crystal samples must be quickly removed after processing and stored in a clean and dry container to prevent the absorption of moisture.

The crystal wafers were cut from the last grown part and polished to a mirror finish. Under a polarized light microscope, only a few separate grains were found in the peripheral area. No inclusions, cracks, or grain boundaries were observed in the inner area of about 4 mm diameter. Figure 1(b) displays a crystal with dimensions up to $5 \times 2 \times 1$ mm$, which was mechanically cleaved from the central region of the last grown part of the ingot with a sharp steel pin.

B. Composition and structure

There can be a concentration gradient of Na either along or across the crystal growth direction. In order to minimize
SINGLE-CRYSTAL GROWTH AND ANISOTROPIC...

this possibility, the crystal wafers were cut from the last grown part in the range of 2–3 mm from the end. Three pieces of crystal were cut from the same crystal wafer, and all three pieces were analyzed by ICP-AES. We found that the Na concentrations of the three pieces of crystal are very close. The average values of Na determined from the three pieces were 0.91, 0.92, and 0.93 for the starting compositions of Na$_{1.00}$CoO$_2$, Na$_{1.05}$CoO$_2$, and Na$_{1.10}$CoO$_2$, respectively. Single-crystal XRD measurements were made on both as-grown crystals. Plate-like crystals were cleaved along the growth direction. Typical XRD patterns are shown in Fig. 2. All the peaks were indexed to be the $(h,k,l)$ planes, and Fig. 3 presents the refinement pattern of the Na$_{0.92}$CoO$_2$ single crystal. The observed diffraction intensities and the calculated patterns are represented by plus signs and solid lines, respectively. The curves at the bottom represent the difference. Short bars below the observed and calculated patterns indicate the positions of allowed Bragg reflections.

C. Magnetic anisotropy

The temperature dependence of the susceptibility for the Na$_{0.92}$CoO$_2$ sample, as measured in a field of 1 T oriented either along or perpendicular to the (001) direction, is shown in Fig. 4. Upon cooling, a peak develops around 20.5 K, which is sharper than that observed in two-layer Na$_{0.82}$CoO$_2$ single crystal.$^{20}$ The following sharp decrease of the (001) direction susceptibility around 19.6 K heralds an antiferromagnetic transition with ordered moments along $c$. The inset in Fig. 4 shows that the transition is only weakly affected by the field. The upturn of the curves below 14 K appears to be due to paramagnetic contributions from impurities; this upturn is suppressed in a field of 5 T.

The magnetization is very sensitive to the presence of Co$_3$O$_4$ and CoO, which are antiferromagnets with $T_N$=35 and 292 K, respectively. No other transitions in the susceptibility have been found from 20.5 K to room temperature for any of the samples, indicating high quality of the single-crystal samples. This is consistent with x-ray diffraction measurements, which exhibit no traces of impurities.

The temperature dependence of the susceptibility for the Na$_{0.93}$CoO$_2$ sample measured in a field of 1 T parallel and perpendicular to the (001) direction is shown in Fig. 5. It can be seen that the antiferromagnetic transition at 19.6 K seen in the Na$_{0.92}$CoO$_2$ sample is absent for the Na$_{0.93}$CoO$_2$ sample, as measured in a field of 1 T oriented either along or perpendicular to the (001) direction.

magnetic for x tiferromagnetic as what have been observed in crystals susceptibility decreased as the applied magnetic field increased below this temperature. For case of results at different parallel magnetic fields. Considering the fact that the different magnetic phases, antiferromagnetic and paramagnetic.

As to why such a little difference in the composition could cause a big difference in the magnetic properties of the α-NaCoO2 single crystals, we believe that the compositions of x=0.92 and 0.93 just locate at a boundary (in a magnetic phase diagram) that separates two different regions with different magnetic phases, antiferromagnetic and paramagnetic. Considering the fact that the α phase only forms for x=0.9 up to x=1.0, the compounds with x=0.90 and 0.92 are antiferromagnetic as what have been observed in crystals grown by the flux method21 and in our crystals presented in this work. For x>0.92, samples are paramagnetic (as in the case of x=0.93 of our crystals) and eventually become non-magnetic for x=1.6.

In order to analyze the T dependence of the anisotropic susceptibility quantitatively, we plotted $\chi_{ab}(T)$ versus $\chi_c(T)$ with an implicit parameter $T$ for both single crystals (Fig. 6). The analysis mentioned in Ref. 22 leads to the relation between $\chi_{ab}(T)$ and $\chi_c(T)$:

$$\chi_{ab}(T) = (g_{ab}/g_c)^2 \chi_c(T) + \left[\chi_0^{ab} - (g_{ab}/g_c)^2 \chi_0^c\right]$$

The fitted slope of the data in Fig. 6 corresponds to the ratio $(g_{ab}/g_c)^2$. The samples with x=0.91, 0.92, and 0.93 have $g_{ab}/g_c=1.40, 1.29$, and 1.12, respectively. These results indicate that the derived anisotropic g-factor ratios $(g_{ab}/g_c)$ decrease significantly with a little change in sodium concentration, indicating that the physical properties of the three-layer NaCoO2 should be very sensitive to the Na contents.

We fit the temperature dependence of the susceptibility under a 1 T field for the x=0.91, 0.92, and 0.93 single crystals to a modified Curie-Weiss law, $\chi=\chi_0+C/(T-\theta)$, by the least-squares calculation, where $\chi_0$, C, and $\theta$ are the temperature independent susceptibility, the Curie constant, and the asymptotic Curie temperature, respectively. The fitting parameters for both field orientations in the range T =50–300 K are given in Table II. The fitted values for the

SINGLE-CRYSTAL GROWTH AND ANISOTROPIC...

powder average are also listed. As expected, we find that the Curie constants for $H_{\parallel ab}$ and $H_{\parallel c}$ are significantly different for these single-crystal samples, which may arise from an anisotropic $g$ factor. The negative $\theta$ suggests antiferromagnetically interacting spins.

The three-layer $\text{Na}_x\text{CoO}_2$ has a hexagonal crystal structure with in-plane and out-of-plane parameters $a=2.887$ Å and $c=15.60$ Å, with space group $R-3m$. It is obvious that the crystal structure is highly anisotropic. Therefore, the difference in the in-plane and out-of-plane magnetic properties is expected, and it has been, indeed, observed in our crystal samples. However, the occurrence of in-plane anisotropy seems hard to predict. Nevertheless, we have noticed that an in-plane anisotropy in two-layer $\text{Na}_x\text{CoO}_2$ compounds has just recently been observed using the neutron diffraction technique. Therefore, there could be a possibility of in-plane anisotropy in our three-layer $\text{Na}_x\text{CoO}_2$ crystals.

Although the determination of the $a$ direction in the $ab$ plane is very difficult for the $\text{Na}_x\text{CoO}_2$ crystals, we can determine how the magnetization changes when magnetic field is rotated in the $ab$ plane. Therefore, the $ab$ in-plane magnetic anisotropy is measured by the following procedures for our crystals: we first measured our sample with the field along one direction in the $ab$ plane (the $ab1$ direction as indicated in the inset of Fig. 7), then measured again by rotating the sample 90° in the $ab$ plane as indicated by the $ab2$ direction in the same inset. A large crystal (4×4×1 mm$^3$) with $x=0.91$ was chosen for the in-plane anisotropy study, and its out-of-plane anisotropy was also measured.

The temperature dependence of the susceptibility ($\chi$-$T$) for the $x=0.91$ sample which was measured in the field of 1 T is shown in Fig. 7. It can be seen that although the susceptibilities measured along the two in-plane directions show the same trend with temperatures, they have about 10%–18% difference in magnitude over a wide range of temperatures. The two in-plane susceptibilities are very different from that along the $c$ direction. A crossover is clearly seen at 120 or 180 K, respectively, which is also seen in the $x=0.92$ sample at 120 K, as shown in Fig. 4. The above results indicate that the in-plane anisotropy exists in the $x$-phase $\text{Na}_x\text{CoO}_2$ crystals. The in-plane and out-of-plane Curie constants are calculated by fitting to the modified Curie-Weiss law, and their values are given in Table II. It can be seen that the $C$ values for the $ab1$ and $ab2$ in-plane directions are very close (0.037 and 0.049). However, the difference between the in-plane and out-of-plane Curie constants is big, which is similar to what has been obtained for the $x=0.92$ and 0.93 crystals. The difference in the in-plane Curie constants is apparently due to the in-plane anisotropy of the three-layer $x$-phase $\text{Na}_x\text{CoO}_2$ crystals. Our observation on the in-plane anisotropy in the $\alpha$-$\text{NaCoO}_2$ single-crystal samples is in agreement with what has been reported for two-layer $\gamma$-$\text{NaCoO}_2$ phase. However, we point out that it is very hard to align the crystal in the $ab$ plane perfectly for each measurement. Therefore, the less accurate alignment of the $ab$ plane could also contribute to the difference in the susceptibilities in the $ab$ plane. Further work is needed for the in-plane anisotropy measurement with very accurate alignment in the $ab$ plane.

IV. CONCLUSIONS

In summary, large, nonstoichiometric $\alpha$-$\text{Na}_x\text{CoO}_2$ high quality single crystals can be grown using the TSFZ method under oxygen atmosphere. As-grown single crystals are more sensitive under ambient conditions compared with two-layer crystals. The structure derived from the single crystals agrees with the reported powder samples. The lattice parameter $c$ decreases with increasing Na content, while $a$ remains constant. The compound was found to be antiferromagnetic at $T_N \simeq 20$ K for $x=0.91$ and 0.92, and paramagnetic for $x=0.93$. The in-plane and out-of-plane anisotropies were observed for the $x=0.91$ crystals. The anisotropic $g$-factor ratios ($g_{ab}/g_c$) along $H_{\parallel ab}$ and $H_{\parallel c}$ decrease significantly as the sodium composition is slightly increased.
