Modelling Demand for Broad Money in Australia

Abstract

The existence of a stable demand for money is very important for the conduct of monetary policy. It is argued that previous work on the demand for money in Australia has not been very satisfactory in a number of ways. This paper examines the long- and short-run determinants of the demand for broad money employing the Johansen cointegration technique and a short-run dynamic model. Using quarterly data for the period 1976:3-2002:2, this paper finds, inter alia, that the demand for broad money is cointegrated with real income, the rate of return on 10-year Treasury bonds, the cash rate and the rate of inflation.

Modelling Demand for Broad Money in Australia

The existence of a stable demand for money is very important for the conduct of monetary policy. It is argued that previous work on the demand for money in Australia has not been very satisfactory in a number of ways. This paper examines the long- and short-run determinants of the demand for broad money employing the Johansen cointegration technique and a short-run dynamic model. Using quarterly data for the period 1976:3-2002:2, this paper finds, *inter alia*, that the demand for broad money is cointegrated with real income, the rate of return on 10-year Treasury bonds, the cash rate and the rate of inflation.

JEL classification numbers: E41, E52, and C32.

Keywords: Demand for Money, Money and Interest Rates, Cointegration, Australia.

1 Introduction

The existence of a stable demand for money in the long run is very important in the implementation of monetary policy. Australia's approach to monetary policy has undergone significant changes since 1976. From the mid-1970s until 1985, based on the assumption of a strong and persistent relationship between inflation and the supply of money, monetary policy was conducted by targeting the annual growth of M3. However, in 1985 this policy was abandoned because deregulation of the financial system made M3 a misleading guide to the stance of monetary policy (Grenville, 1990). From 1985 to 1989 a "checklist approach" was adopted, whereby a multitude of indicators such as, monetary aggregates, the GDP growth rate, the shape of the yield curve, exchange rates, and the unemployment rate were considered prior to the implementation of monetary policy. The checklist approach was also unsuccessful and finally discontinued in 1989 due to the impossibility of monitoring and considering the large number of indicators outlined above.

Since 1989, approach taken by the Reserve Bank of Australia (RBA) to monetary policy has been to set the official cash rate in the money market. Following many other OECD countries, inflation targeting has become the ultimate goal of monetary policy in Australia since 1993 (Juttner, Kim, and Hawtrey, 1997). It should be borne in mind that a stable money demand function is still important in this new era of inflation targeting (Hayo, 1999).

A number of studies have already been undertaken to investigate the demand for money in Australia. The review of literature on the demand for money in Australia briefly presented below indicates a growing consensus among economists that broad money (BM) should be considered as an appropriate indicator of monetary aggregate, particularly after the 1980s. However, from 1960 to 1980 there were several studies which reported conflicting results on this issue.

Cohen and Norton (1969) can be considered as pioneers of money demand analysis in Australia. Using a modified stock adjustment model, they estimate several money demand functions with the limited available quarterly data for various monetary aggregates in Australia. Unlike Adams and Porter (1976) who argue against stability of M1, Pagan and Volker (1981) employ a conventional specification of the demand for money function and found a stable relationship for M1. Sharpe and Volker (1977) and Lim and Martin (1991) in their study of M3 in Australia argued for the stability of the money demand function, while Blundell-Wignall and Thorp (1987), and Orden and Fisher (1993) modelled M1, M3, and BM, and found exactly the opposite. de Brouwer, Ng and Subbaraman (1993) and Juselius and Hargreaves (1992) use Australian data and correctly conclude that the number of cointegrating vectors and their stability are very sensitive to the choice of scale variable, *e.g.* GDP or GNE (gross national expenditure), and the measure of money. Using the Johansen test, de Brouwer, Ng and Subbaraman (1993) have also examined various measures of money, different interest rates,

and scale variables, and concluded that there is evidence of cointegration between money, income and the interest rate, particularly for BM.

Using the Engle and Granger two-step methodology and quarterly data for the 1970:1-1993:1 period, Hoque and Al-Mutairi (1996) find a long-run relationship between narrow money, output, the interest rate, and price level. They conclude that this long-term relationship shows no sign of instability in the face of financial innovation and deregulation in the 1980s. It can be argued that the model formulated by Hoque and Al-Mutairi is misspecified as it includes only one interest rate (the two-year Treasury bill rate) in the equation for money demand, ignoring the process of financial asset substitution.

Felmingham and Zhang (2001) have identified this misspecification, and included a more appropriate measure of opportunity cost of holding money (*i.e.* the interest rate spread defined as the difference between short- and long-run interest rates) in their cointegrating vector of the demand for BM. They employ the Johansen cointegration technique and find that there exists a cointegrating vector linking BM with real GDP, the interest rate spread and inflation over the period 1976:3-1998:4. They have also performed several residual-based tests for cointegration to identify a structural break in their long-run relationship for BM. Felmingham and Zhang (2001) conclude that this long-run relationship was subject to regime shifts in 1991.

Based on an estimated income elasticity of 1.21, they describe money as a luxury good but in the literature this “is customarily interpreted as proxying omitted wealth effects” (Coenen and Vega, 2001, p.728.). Felmingham and Zhang (2001, p.150) also erroneously deflate nominal GDP with the consumer price index (CPI) and also assume that the semi-elasticities of the interest rate on money itself and the interest rate outside money have equal magnitude but with opposite signs without testing such an important restriction. Given that this assumption is rejected (see section III), one can argue that their estimated coefficients are somewhat biased.

Furthermore, they have not estimated a short-run dynamic model for BM and no weak exogeneity testing was undertaken either.

This paper updates the sample and addresses the problems and shortcomings associated with the previous work on the demand for BM. The structure of the paper is as follows. In Section II a theoretical model is postulated which captures the long-run demand for money using the Johansen multivariate cointegration technique. Definitions of the variables, sources of the quarterly data employed as well as the unit-root results using the Augmented Dickey-Fuller (ADF) and the Kwiatkowski-Phillips-Schmidt-Shin (KPSS) tests are presented in Section (III). The empirical econometric results for the long- and short-run demand for money, as well as policy implications of the study are also discussed in this section. Section IV provides some concluding remarks.

II Theoretical Framework

Conventionally the demand for money is specified as a function of real income, a long-run interest rate on substitutable non-money financial assets, a short-run rate of interest on money itself, and the inflation rate. More specifically, following, *inter alia*, Ericsson (1998), Beyer (1998) and Coenen and Vega (2001), the demand for money function is specified as follows:

$$m_t - p_t = \gamma_0 + \gamma_1 y_t + \gamma_2 RL_t + \gamma_3 RS_t + \gamma_4 \Delta p_t + \varepsilon_t \quad (1)$$

where m is nominal money demanded, p is the price level, y is a scale variable, RL is the long-run rate of return on assets outside of money and RS is the short-run rate of interest on money itself. All variables shown in lowercase (*i.e.* m , y , and p) are in logs and the remaining variables (*i.e.* RL and RS) are in levels. As a result, γ_1 denotes the income elasticity of the demand for money, whereas γ_2 , γ_3 , and γ_4 are semi-elasticities of RL , RS , and the inflation rate with respect to

money demand, respectively. In practice if γ_2 and γ_3 have coefficients of equal magnitude but opposite signs, equation (1) can also be rewritten in the following form:

$$m_t - p_t = \gamma_0 + \gamma_1 y_t + \gamma_2 (RL_t - RS_t) + \gamma_4 \Delta p_t + \varepsilon_t \quad (2)$$

Following earlier studies mentioned above, in order to avoid dealing with I(2) variables (m and p), equations (1) and (2) are usually employed to model real money balances, supporting the price homogeneity assumption. The expected sign and magnitude of the coefficient for the scale variable is as follows: if $\gamma_1=1$, the quantity theory applies; if $\gamma_1=0.5$, the Baumol-Tobin inventory-theoretic approach is applicable; and if $\gamma_1>1$, money can be considered a luxury. According to Ball (2001), an income elasticity of less than unity has a number of implications for monetary policy. For instance, one may conclude that the Friedman rule is not optimal in this case and the supply of money should grow more sluggishly than output to achieve the goal of price stability (Ball, 2001, p.36). For a detailed discussion of controversy about the quantity theory see Laidler (1991).

It is also expected that RL , as a proxy for the yields on outstanding Treasury bonds, has a negative sign or $\gamma_2<0$, whereas the coefficient for the short-run rate of interest is positively correlated with money demand, or $\gamma_3>0$. The annualised rate of inflation $\Delta p = \Delta_4 p_t = \ln(P_t) - \ln(P_{t-4})$, is considered as a proxy to measure the return on holdings of goods and its coefficient should thus be negative, *i.e.* $\gamma_4<0$, as goods are an alternative to money. The exclusion or inclusion of inflation in this equation is an issue of dynamic specification. According to Ericsson (1993, p.309), “exclusion imposes equality of the short- and long-run elasticities of nominal money with respect to prices. Often, that restriction is resoundingly rejected.” For a comprehensive discussion of the literature on money demand see also, *inter alia*, Laidler (1993) and Hoffman and Rasche (2001).

If empirical results do not reject the null hypothesis of $\gamma_1=1$, then the (inverse) long-run velocity of BM can be obtained by:

$$(m_t - p_t - y_t) = \gamma_0 + \gamma_2 RL_t + \gamma_3 RS_t + \gamma_4 \Delta p_t + \varepsilon_t \quad (3)$$

In order to have a valid model for the money demand function, there should be at least one cointegrating vector in the system. The Johansen (1991, 1995) multivariate cointegration technique is used in this paper to test the existence of a long-run equilibrium relationship among the variables specified in equation (1). A brief description of this technique is presented below.

Let us consider the following VAR of order q :

$$y_t = A_1 y_{t-1} + A_2 y_{t-2} + \dots + A_q y_{t-q} + \varepsilon_t \quad (4)$$

where y_t is a k -vector of $I(1)$ variables (*e.g.* in this study $k=5$ and the variables are $m-p$, y , RL , RS , and Δp), and ε_t is a vector of white noise residuals. Following Johansen (1991, 1995) equation (4) can also be rewritten as:

$$\Delta y_t = \Pi y_{t-1} + \sum_{i=1}^{q-1} \Gamma_i \Delta y_{t-i} + \varepsilon_t \quad (5)$$

where $\Pi = \sum_{i=1}^q A_i - I$, and $\Gamma_i = -\sum_{j=i+1}^q A_j$

The rank (r) of Π determines the number of cointegrating vectors. If Π has a reduced rank (*i.e.* $r < k$), then there exist $k \times r$ matrices α and β each with rank r , where $\Pi = \alpha\beta'$ and $\beta'y_t$ is stationary. The elements of α represent the adjustment parameters and each column of β in the literature is referred to as the cointegrating vector. Thus the important issue is how to determine the number cointegrating vectors (or r). In this paper both the trace statistics and the maximum eigenvalue statistics will determine r . The trace statistics test the null hypothesis of r cointegrating relations against the alternative of k cointegrating equations. On the other hand, the

maximum eigenvalue statistics test the null of r cointegrating vectors versus the alternative of $r+1$ cointegrating relations. For more details see Johansen (1991, 1995).

An important step before using the Johansen multivariate technique is to determine the time series properties of the data. This is an important issue since the use of non-stationary data in the absence of cointegration can result in spurious regression results. To this end, two unit root tests, *i.e* the ADF test, and the Kwiatkowski-Phillips-Schmidt-Shin (KPSS, 1992) test, have been adopted to examine the stationarity, or otherwise, of the time series data. In this paper the lowest value of the Akaike Information Criterion (AIC) has been used as a guide to determine the optimal lag length in the ADF regression. These lags augment the ADF regression to ensure that the error term is white noise and free of serial correlation.

In addition to the ADF test, a KPSS test has been calculated for all the variables. Unlike the ADF test, the KPSS test has the null of stationarity, and the alternative indicates the existence of a unit root. The KPSS test simply assumes that a time series variable (say y_t) can be decomposed into the sum of a deterministic trend, a random walk, and a stationary error term in the following way:

$$y_t = \beta t + \xi_t + \varepsilon_t \quad (6)$$

where ξ_t (a random walk) is given by $\xi_t = \xi_{t-1} + u_t$.

One can now test for the stationarity of y_t by testing $\sigma_u^2 = 0$. This test involves two steps: first one should run an auxiliary regression of y_t on an intercept and a time trend t and save the OLS residuals (say e_t) and compute the partial sums $S_t = \sum_{i=1}^t e_i$; and second, compute the following KPSS statistic:

$$\text{KPSS} = T^{-2} \sum_{t=1}^T S_t^2 / s^2(I) \quad (7)$$

where $s^2(l) = T^{-1} \sum_{t=1}^T e_t^2 + 2T^{-1} \sum_{s=1}^l w(s, l) \cdot \sum_{t=s+1}^T e_t e_{t-s}$. Following KPSS, the Bartlett window, where $w(s, l) = 1 - s/(l+1)$, has been used to correct for heteroscedasticity and serial correlation. A maximum of 8 lags was chosen for the lag truncation parameter (l) in the testing procedure.

III Empirical Results and Policy Implications

The nominal demand for BM rose substantially from \$49.2 billion in the third quarter of 1976 to \$546.5 billion in the second quarter of 2002, an average growth of 2.3 per cent per quarter or 9.2 per cent per annum. What are the major long- and short-run determinants of the demand for BM during the last four decades? Based on the theoretical framework discussed in Section (II), the objective of this paper is to answer this question.

Before embarking on our empirical quest, it is important to look at the sources and definitions of the data presented in Table 1. Quarterly time series data employed for the period 1976:3-2002:2 are as follows: nominal broad money (m), the consumer price index (p), real GNE (y), ($m-p$), the rate of return on 10-year Treasury bonds as a proxy for RL , and the official cash rate as a proxy for RS . The three variables of m , p , and y are seasonally adjusted. Following the literature, RL , RS and the rate of inflation are expressed as fractions, whereas, the other variables are in logs and thus shown in lowercase. According to de Brouwer, Ng and Subbaraman (1993, p.10), BM encompasses “M3 plus borrowings from the private sector by non-bank financial intermediaries (NBFIs), less their holdings of currency and bank deposits”. They also argue that compared with other measures of money, the evidence of cointegration is stronger when BM is modelled as it: a) is less distorted by financial deregulation and innovations; and b) has a more reliable relationship with GNE. Following the literature, in this paper BM is preferred to other narrower measures of money such

as M1 and M3 which can be substantially affected by asset substitution and are also more volatile (Felmingham and Zhang, 2001). de Brouwer, Ng and Subbaraman (1993, p10), believe that “selection of the income and interest rate variables is largely an empirical matter.”

However, the choice of interest rates depends on the measure of money being modelled. While Felmingham and Zhang (2001) considered the weighted average 5- and 10-year Treasury bond interest rates as a proxy for *RL*, and the weighted average of interest rate paid on saving deposits by AMMD (authorised money market dealers), as a proxy for *RS*, this study uses the cash rate and the interest rate on the 10-year Treasury bonds as proxies for *RS* and *RL*, respectively. The rationale for this decision is twofold: the first reason relates to the issue of data reliability, and the second pertains to the nature and recognition of the cash rate as a policy variable in practice. These two reasons are discussed below in more detail.

First, as seen from Figure 1, the cash rate and the AMMD rate move very closely to each other particularly after 1983 (when the exchange rate was floated). However, the data on the cash rate seem more reliable, as for example from 1983:3 to 1983:4 the AMMD rate decreased abnormally from 9.7 per cent to 4.6 per cent whereas the cash rate only declined from 10.7 to 8.3 per cent. It can be argued that the average AMMD rate only represented “authorised dealers” before the deregulation and thus it did not cover the interest rates paid by NBFIs, which played a very important role in Australia’s financial system over this period. Therefore, the use of the AMMD rate may create a measurement error in the proxy for *RS*.

[Table 1 and Figure 1 about here]

The second reason pertains to the purpose of this study. The motivation for this study is to estimate the short- and long-run impact of (say) a 1 per cent change in a policy variable which can be controlled and changed directly by the RBA as a policy variable. This variable is the cash rate and the RBA is the only agent which has exclusive right to set and fine tune it. The official

cash rate is considered a good proxy for RS as it exerts a great influence on all other interest rates in the money market, *e.g.* those of Treasury notes and 90-day bank bills.

Ericsson (1998) suggests that long-run rates should not be included in the demand equation for $M1$. However, if a broader definition of money is modelled, it is essential to incorporate longer-term interest rates in the demand for money function so as to capture financial asset substitutions. This paper examines the demand for “broad” money, and as a result RL is best proxied by a “long-run rate” such as the rate of interest on 10-year Treasury bonds, a security with the longest maturity for which the quarterly time series data are available. The broader the definition of money, the longer rates would be more relevant. Besides, the use of a weighted average of 5- and 10-year Treasury bonds, as employed by Felmingham and Zhang (2001), may be susceptible to measurement errors associated with likely inaccuracy of “true weights” in the computation of such a measure.

Prior to undertaking an empirical investigation of the sources of demand for BM , it is essential to determine the time series properties of the data. In order to make robust conclusions about stationarity or otherwise of the data, the ADF and the KPSS tests are utilised. The empirical results of the ADF tests are summarised in Table 2. According to the results of the ADF test, both m and p are $I(2)$, whereas $m-p$ is $I(1)$, indicating that p and m become stationary after second differencing, whereas $m-p$ reaches stationarity after first differencing. This is the main reason why in many studies ($m-p$), instead of m , is modelled in equation 1. All the other variables, *i.e.* (y , RL , RS , and Δp) are $I(1)$.

[Table 2 about here]

Table 3 uses equation (7) and presents the results of the KPSS test for level (with constant only) and trend stationarity (with both a constant and trend) up to a maximum of 8 truncation lags (l). As seen from Table 3, irrespective of the number of truncation lags and

consistent with the ADF test results, m and p are again $I(2)$ and y , RL and RS are $I(1)$. It should be noted that, according to the KPSS test results, the variable $(m-p)$ is $I(1)$ using a lag truncation parameter of up to 5 but the addition of more lags results in the reversal of this conclusion. In other words, $(m-p)$ is $I(1)$ if one considers the KPSS statistic from lag 0 to lag 5 but with the use of 6 to 8 lags the KPSS test fails to reject stationarity of this variable. Given the fact that in most cases the problem of serial correlation for quarterly time series data is likely to be of order 1 to 4, a maximum upper bound of 4 truncation lags (l) will be enough to ensure that autocorrelation is corrected in the KPSS test. Therefore it is assumed that $(m-p)$ is also $I(1)$. In sum, the ADF and KPSS tests for unit roots support the view that m and p are $I(2)$, and the remaining variables, which will be used in equation (1), viz., $(m-p)$, y , RL , RS , and Δp , are $I(1)$ for the sample under investigation.

[Table 3 about here]

Since all the variables in equation 1 are $I(1)$, the Johansen (1991, 1995) multivariate cointegration technique can now be used to test the existence of a long-run equilibrium relationship for BM. In addition to the five variables discussed earlier, a dummy variable (du) has been considered. This intercept dummy variable is equal to 1 before 1983 and otherwise zero. The inclusion of this dummy variable (du) related to the Australian currency being floated in 1983, producing an important effect on the financial and monetary system. It is assumed that this dummy variable affects the vector error correction (VEC) model but not the cointegrating vector(s). Following Coenen and Vega (2001), an unrestricted intercept and a linear trend in the variables but not in the cointegrating vectors enter the system. The first important step in this test is to determine the optimal lag length (q) in equations (4) or (5). Allowing for an upper band of 4 lags, three lag selection criteria of the FPE (final prediction error), the sequential modified LR (likelihood ratio) test statistic and the AIC have been employed to determine q . Based on these

criteria (not reported here but available from the author upon request), the optimum lag length is $q=2$. There are a number of other recent studies modelling the quarterly demand for money that have also used an optimal lag length of two. See for example (Beyer, 1998), Coenen and Vega (2001), and Schmidt (2001). Various diagnostic tests indicate that the system of equations with two lags is well-behaved.

However it should be noted that the rank (r) of Π in this study is not sensitive to the lag length. Both the trace and max-eigenvalue tests, using a variety of lags ranging from 1 to 5 in separate VAR models, reject a zero cointegrating vector in favour of one cointegrating vector at the 1 per cent significance level. Table 4 reports the results of the Johansen multivariate cointegration test on the demand for BM as formulated in equation (1). As seen there is robust evidence of one cointegrating vector at the 1 per cent level. Due to space limitations, the cointegration test results using other lags (i.e. 1, 3, 4, and 5 lags) are not reported here but are available from the author on request.

[Table 4 about here]

From Table 5 the long-run parameters are seen to be of consistent sign and orders of magnitude and highly significant. It should be noted that the eigenvalue associated with the first vector (0.323) is considerably higher than those corresponding to the other vectors, thereby validating that there exists a unique cointegrating vector in the system. As can be seen from the results obtained from the unrestricted cointegrating vector in Table 5, the long-run demand for BM ($m-p$) is positively related to the own-rate (RS) and negatively to both the rate of return on other substitutable financial assets (RL) and the annualised rate of inflation.

[Table 5 about here]

Table 5 also shows the estimated adjusted coefficients (α_s) which can be used to test for weak exogeneity. The adjustment coefficients contain weights with which cointegrating

vector(s) enter short-run dynamics. Given that this study finds only one cointegrating vector, Table 5 presents the first column of the α matrix. These coefficients measure the speed of the short-run response to disequilibrium occurring in the system. Before proceeding any further, it is essential to test for weak exogeneity of the four variables on the right hand side of equation (1) with respect to $(m-p)$. The Johansen method enables analysts to test for weak exogeneity by imposing zero restrictions on the weighting coefficients of α_y , α_{RL} , α_{RS} , and $\alpha_{\Delta p}$. One should note that the *ec* term is significant and correctly signed (-0.153) in the VEC equation for $(m-p)$.

Table 6, *inter alia*, presents the test results for separate and joint restrictions on the weighting coefficients. As can be seen, using separate zero restrictions on the corresponding α s, the *ec* term, while highly significant for $(m-p)$, is not significant in the short-run dynamic equations for y , RL , RS , and Δp . The weak exogeneity test, by imposing the joint zero restriction of $\alpha_{RL}=\alpha_{RS}=\alpha_{\Delta p}=0$, reveals that the null cannot be rejected at the 1 per cent level as $\chi^2(3)=5.8$ [probability=0.12]. However, the joint restriction of $\alpha_y=\alpha_{RL}=\alpha_{RS}=\alpha_{\Delta p}=0$ can be rejected at 4 per cent. See Table 6.

[Table 6 about here]

On the basis of imposing separate and joint restrictions on the adjustment coefficients one can conclude that while three variables of RL , RS and Δp are weakly exogenous with respect to $(m-p)$ but y is not. Therefore a single-equation and OLS cannot be used to model short-run dynamics of $\Delta(m-p)_t$ due to the simultaneity problem arising from y not being weak exogenous. That is why a number of studies have modelled $\Delta(m-p-y)_t$ rather than $\Delta(m-p)_t$, imposing equality of the long- and short-run income elasticities, *e.g.* Hayo (2000) in the case of the demand for money in Austria. If the null of $\gamma_1=1$ is not rejected, then one can model

short-run dynamics of $\Delta(m-p-y)_t$ instead of $\Delta(m-p)_t$ without facing the weak exogeneity problem of y .

As seen from Table 5, the estimated long-run income elasticity (1.10) is reasonably close to unity which is consistent with the quantity theory of money and other studies for developed countries, *e.g.* Beyer (1998) in his study of M3 in Germany, Coenen and Vega (2001) in their recent study of M3 in the Euro area, and Ericsson (1998) in his analysis of the narrow demand for money in the UK. Nevertheless, one needs to test formally the $\gamma_1=1$ assumption on the cointegrating vector. Table 6 also presents the LR test result for this restriction. Given that $\chi^2(1)=3.84$ [probability=0.05], one can “marginally” reject the null of $\gamma_1=1$ at 5 per cent level but the null will not be rejected at the 1 per cent level. Here there is a dilemma. As mentioned earlier one cannot proceed with a single-equation capturing short-run dynamics of the demand for money unless this assumption ($\gamma_1=1$) is invoked. Therefore, I have contentiously ignored the “margin of 5 percent level” and not rejected the null by sticking to a significance level lower than 5 per cent. Since the long term elasticity of 1.10 is quite close to one and the fact that the rejection occurs at the margin of 5 per cent, the assumption of $\gamma_1=1$ is not rejected.

Attention is now placed on a restricted version of the cointegrating vector. This restricted cointegrating vector links $(m-p-y)$ with RL , RS and Δp , implying that the long- and short-run income elasticities are equal. The cointegration results under the assumption of $\gamma_1=1$ for this restricted model are also shown in Table 5. The adjustment coefficient for the dependent variable has changed slightly from -0.15 in the non-restricted vector to -0.13 in the restricted cointegrating vector. This coefficient is highly significant, correctly signed and within an acceptable range. For example Coenen and Vega (2001, p737) in their study of M3

in the Euro area and Beyer (1998, p.60) in his study of M3 in Germany found the corresponding adjustment coefficient to be -0.132 and -0.141, respectively. The restricted cointegrating vector is also presented below.

$$(m_t - p_t) = y_t - 3.7 - 3.65RL_t + 2.38RS_t - 0.45\Delta p_t \quad (8)$$

At this stage one may also want to test if $\gamma_2 = -\gamma_3$. Using the cointegrating vector in equation (8), this restriction has been tested and the result from the LR test is presented in Table 6. Given that $\chi^2(1)=5.1$ [probability=0.02], the null hypothesis of $\gamma_2 = -\gamma_3$ is rejected at the 2 per cent significance level, indicating that RL and RS do not have coefficients of equal magnitude but opposite signs. Thus equation (8) is used to analyse the long-term determinants of the demand for BM. One should note that the most recent study undertaken by Felmingham and Zhang (2001) on the demand for BM in Australia has not tested this hypothesis and assumed that $\gamma_2 = -\gamma_3$.

As seen from equation (8), consistent with the quantity theory of money supporting a long-run income elasticity of unity, a one per cent increase in real income stimulates the real demand for BM by one per cent. Given that the estimated coefficients of -3.65 , $+2.38$ and -0.45 are the semi-elasticities for RL , RS and Δp , respectively, one can convert them to elasticities by multiplying each one of them by the value of its corresponding variable in each quarter. Thus the magnitudes of the resulting elasticities vary depending on the value taken by these variables. For instance, given that the actual data for RL , RS , and Δp in the second quarter of 2002 were 0.061, 0.0447 and 0.028, respectively, the corresponding elasticities would be -0.22 (0.061 times -3.65), 0.11 (0.0447 times 2.38), and -0.01 (0.028 times 0.45).

Therefore, *ceteris paribus*, if the RBA had increased the cash rate in the second quarter of 2002 say by 10 per cent (from 0.0447 to 0.0492), this would have led to a rise of

1.1 per cent in the demand for BM. On the other hand, a similar 10 per cent rise in the inflation rate and the rate of return on 10-year Treasury bonds in 2002:2 would have resulted in a 0.1 and 2.2 per cent fall in the demand for BM, respectively. As $|\gamma_2| > |\gamma_3|$, an expected increase in both the cash rate and the rate of return on 10-year Treasury bonds does not have equal effect. If the rate of return on the 10-year Treasury bonds (RL) had increased by x per cent in 2002:2 and the RBA wanted to keep real money balances unchanged, then the cash rate should be raised by 2 times x per cent because the RL elasticity is twice as larger as the RS elasticity. Consistent with theoretical postulates discussed in Section (II), it is also found that an increase in the rate of inflation encourages agents to diversify their portfolios in the economy by acquiring real assets.

Using the resulting residuals (the ec term) from the long-run relationship in equation (8), one can estimate a VEC model which captures the short-run dynamics of the demand for BM. That is:

$$\Delta(m - p - y)_t = \varphi_0 + \sum_{i=0}^{q_1} \varphi_{1i} \Delta RL_{t-i} + \sum_{i=0}^{q_2} \varphi_{2i} \Delta RS_{t-i} + \sum_{i=0}^{q_3} \varphi_{3i} \Delta \Delta(p)_{t-i} + \sum_{i=1}^{q_4} \varphi_{4i} \Delta(m - p - y)_{t-i} + \theta EC_{t-1} + v_t \quad (9)$$

where φ_{ij} are the estimated short-term coefficients; θ is the feedback effect or the speed of adjustment, whereby short-term dynamics converge to the long-term equilibrium path; and the lagged dependent variables are added to ensure that v_t (or the residual) is white noise. See Hendry, Pagan and Sargan (1984) for a concise discussion of dynamic specification.

Starting with a maximum lag of four for q_1 to q_4 , the general-to-specific methodology is now used to omit the insignificant variables in equation (9) on the basis of a battery of maximum likelihood tests. This method of analysis has also been used in other studies. For example see Ericsson, Hendry and Tran (1994), and Hayo (2000). Using $I(0)$ variables in the

estimating procedure, joint zero restrictions are imposed on explanatory variables in the general model or equation (9) to obtain the most parsimonious and robust estimators. The empirical results for the parsimonious model capturing short-run dynamics for money demand are presented in Table 7. As can be seen, the estimated equation for short-run dynamics passes each and every diagnostic test. See Otto (1994) for a concise discussion of diagnostic tests and their importance in the context of the demand for money.

The estimated coefficients have been sensibly signed, with the change in the rate of return on non-financial assets (as proxied by $\Delta^2 p_t$) and the interest rate on assets outside of money (as indicated by the coefficient on ΔRL_{t-1}) having negative semi-elasticities of -0.379 and -0.409 , respectively. As expected, changes in the cash rate (ΔRS_{t-3} , and ΔRS_{t-4}) exert a lagged positive impact on money demand. Furthermore, the feedback coefficient for the ec term is highly significant, validating the significance of the cointegration relationship in the short-run model for money demand. The magnitude of the estimated coefficient for ec indicates that the lagged excess money will reduce holdings of money by 8 per cent in each quarter.

[Table 7 about here]

One problem associated with the analysis of the demand for money is non-constancy or instability of estimated coefficients which can create economic and econometric complications in deriving any inference from the empirical model. Given extensive financial deregulation and innovations introduced in the 1980s, parameter constancy is pivotal in modelling money demand in Australia. Therefore, the estimated short-run model has been evaluated by a number of recursive stability tests which are displayed in Figure 2 in the

following order: $\begin{bmatrix} a & b & c \\ d & e & f \\ g & h & i \end{bmatrix}$

[Figure 2 about here]

where panel (a) displays the recursive residuals; panel (b) depicts the CUSUM test; panel (c) shows the CUSUM of squares; and panels (d) to (i) present the recursively estimated 6 coefficients (excluding the intercept) over the period 1979:3-2002:2 in the same order that these coefficients appear in Table 7 (from top to bottom). These evaluative tests are useful in assessing stability of a model, as recursive algorithms avoid arbitrary splitting of the sample. Overall, the graphical tests for stability reported in Figure 2 reveal that aside from a few minor and insignificant outliers around the 1980s, the test results point to the in-sample constancy of the estimated equation. In particular, the recursively estimated coefficients have remained relatively stable since 1985.

IV Conclusion

After briefly reviewing the relevant literature, this paper determines the long- and short-run drivers of Australia's demand for broad money (BM) using quarterly time series data from 1976:3 to 2002:2. The ADF and KPSS tests for unit roots support the view that all the variables appearing on a standard money demand function are $I(1)$. Therefore, the Johansen cointegration test has been employed to determine the number of the cointegrating vector(s). Cointegration tests clearly indicate that there is a unique cointegrating vector, which links the real demand for BM with real income, the rate of return on 10-year Treasury bonds (RL), the official cash rate (RS), and the annualised rate of inflation (Δ_4p). The estimated long-run income elasticity is very close to unity which is consistent with the quantity theory of money and the results obtained in other studies for developed countries, *e.g.* Beyer (1998) in his study of M3 in Germany, Coenen and Vega (2001) in their recent study of M3 in the Euro area, and Ericsson (1998) in his analysis of the narrow demand for money in the UK.

The long-run semi-elasticities of RL , RS and inflation with respect to the real BM balances are -3.7, 2.4 and -0.45, respectively. The empirical results are broadly in accord with previous studies on the demand for money in developed countries. This paper also presents an error correction model capturing short-run dynamics of money demand. The estimated coefficients in this model are not only highly significant but also have consistent signs and orders of magnitude. The estimated error correction model indicates that the selected interest rates adequately represent the prevailing interest rate regime in the economy. This equation shows no sign of misspecification or instability and passes a battery of diagnostic tests.

The major finding of this paper are summarised below. First, it is plausible to argue that, *ceteris paribus*, the long- and short-run income elasticities are close to one. Second, inflation has an immediate effect (with no lag) on BM in the short-run, suggesting that an increase in inflation can instantly encourage agents to diversify their portfolios in the economy by acquiring real assets. Third, it seems that a change in the cash rate affects the money demand with 3 to 4 quarters lags, whereas the impact of an increase in RL on BM is felt after only one quarter. See Table 7. Therefore, the RBA should pursue a forward looking policy in relation to changes in the cash rate, otherwise the policy may not have a timely and desirable effect. The long- and short-run models estimated for money demand support the view that BM is a predictable monetary aggregate. This study, *inter alia*, shows that the RBA's major policy instrument, changing the official cash rate, is efficacious in affecting BM , a fundamentally important macroeconomic variable. The models developed in this paper can provide useful policy guides for the RBA in its quest for price stability by measuring the impact of a change in the official cash rate on money demand and hence inflation.
