Software interfacing of servo motor with microcontroller

Abstract

Automatic control of DC servo motor in terms of rotation angle has played a vital role in the advance Electromechanical Engineering. Nowadays, the automatic process of motor control using a Personal Computer (PC) is commonly used. The controllers are designed to interface between a Computer and Motor. This paper presents the implementation of PIC Microcontroller with Graphical User Interface (GUI) in Matlab to track the rotational angle of DC servo motor. The movement of slider on GUI will act as an input signal into the Microcontroller to change the rotation angle. A simulation on the performance of the system has been carried out using Proteus software interfaced with Matlab and the controller was tested on real-time application. Results show that the use of PIC Microcontroller and GUI in Matlab is an advantage solution to control the rotational angle.

1. Introduction

DC Servo Motors become an important device in a wide range of industrial applications that require high dynamics on position control such as numerically controlled machinery, robotics, automation and other mechanism where the starting and stopping functions are quickly and accurately [1,2]. These applications require a high-speed control accuracy and good dynamic respond. In robotic applications, servo motors are used to move the robotic arm to a relevant position by means of controllers in the automated manufacturing lines of industries [3, 4]. The rotor construction of servo motors made of special material with less weight to decrease the inertia of armature but capable to produce the necessary magnetic flux. Low rotor inertia increases the capability of immediately starting and stopping during the on-off conditions. The high cost of servo motor becomes a major issue. Therefore, the small-scale manufacturers or users cannot afford to use this type of DC Motor.

DC Servo Motors have a large market share in the Industry Automation & Drive Technologies. The common problems in controlling the servo motor with specific speed and position is the tuning of the parameters. Many different techniques have been proposed in order to cope with the tuning problems. Fuzzy Logic is one of the implemented techniques that have been used to sort out with these problems [4, 5]. The nonlinearity of the servo motor is one of the difficulties in controlling the servo motor. Since the load pressure varies over a wide range under internal parameter variations and external disturbances (load torque variations), these two factors tend to induce a higher degree of nonlinearity [6, 7].

Along with the rapid development of digital and computer control technology, embedded hardware interfacing with the technology of simulink software is undergoing tremendous change. Currently, there are several commercially available embedded hardware interfacing, including advanced RISC machine (ARM), digital signal processing

(DSP), application-specific integrated circuit (ASIC), and field programmable gate array (FPGA). Among them, FPGA have a number of programmable logic resources that make it possible to integrate with microprocessors to form a complete embedded system and perform complex computations in hardware [8]. Many researchers have investigated servo system simulation focusing on principle teaching and maintain training [5, 9, 10, 11, 12]. In [10], an integrated Matlab/Simulink with neural network and LabVIEW was designed to develop a SCADA real-time AC servo motor monitoring control system. Another simulink testing system is introduced in [5] for intelligent robot control using Matlab environment and Turbo C software. Both systems are an effective solution to simplify the data processing with a high performance servo motor tracking scheme.

The traditional test system can no longer meet the rapid development of modern servo system. Therefore, a new kind of automatic testing systems incorporating monitoring software are needed. Ref. [13] discusses the development of simulation software models for two axis servo platform based on the National Instruments LabVIEW. The system is used to evaluate and test an advanced servo control algorithms before being implemented into the actual system. An overall network structure of a developed system in layers was designed in [14]. The system consists of advanced test instruments, user-friendly virtual interface, database server, LAN clients and web server. The connection between LabVIEW and database is realized by using the Database Connectivity Toolkit. To simplify the program, Virtual Instruments Software Architecture was applied with written commands to the buffer, instead of considering any specific communication protocols.

This paper presents the implementation of computer interfacing control for servo motor based on Matlab coding imbedded in microcontroller. Proteus software was used to simulate the hardware and verify the Matlab coding for real time application. In this work, some of the components can be changed easily to upgrade the performance of the system. The work is organized as such that, section 1 gives a brief introduction of DC servo motor with the existing software. A literature review on DC motors and control methods are presented in Section 2. Section 3 presents the principle operation of DC servo motor control. The methodology, software simulation and hardware implementation are outlined in Sections 4 and 5 respectively. The results are discussed in Section 6, while Section 7 drafts the conclusion.

2. A review on dc servo motor control

According to the variety of DC motor, different techniques are designed to control the DC motor and overcome the volatility characteristics of the physical DC motor system itself. The types of DC motor are permanent magnet, winding, stepper and servo, etc. Permanent magnet DC motor has a small size and compact compare to other types of DC motor but the magnetic field strength cannot be varied. Winding DC motors which are shunt-wound, series-wound and compound provide a very high range speed and torque. However, the stepper motor has a higher precise speed control and large torque at low speed but in terms of cost, this type is expensive. Alternatively, servo motor is an important for the application at the industries due to its ability of quick response and precise positioning but motor is expensive [1].

A servo motor is an electromechanical device in which the electrical input determines the position of motor armature. It is actually an assembly of four things: a normal DC

motor, a gear reduction unit, a position-sensing device and a control circuit. Servo motors are used extensively in robotics industry and radio-controlled cars. The implemented types in modern servo systems are AC servo motors based on induction motor designs, DC servo motors based on DC motor designs, DC brushless motors and AC brushless servo motors based on synchronous motor designs. These motors are working in a closed loop control systems where the programmed position of motion and velocity feedback controllers are required [4]. Different studies and researches have been conducted on the servo motor control. Currently, the conventional method of servo motor control is based on proportional integral derivative. Other suggested methods such as artificial intelligence and fuzzy logic were mentioned in Ref [15]. Usually the control method of fuzzy with a fixed set of quantizing factor and scaling factor is often used in the fuzzy control [16]. However, the variations of quantizing factor, scaling factor and control rule in the fuzzy look up table may significantly affect the speed of DC Motor. In addition, with the same set of fuzzy control rule, quantizing factor and scaling factor, the variation of membership function will also affect the control performance of fuzzy control [17, 18].

So far, several approaches for robust control have been proposed and considerable progress was made in this area. The popular techniques primarily intended for linear systems such as linear Quadratic Gaussian control design with loop transfer recovery (LQG/LTR) technique and adaptive or self-tuning control. Among the techniques used mainly for nonlinear systems, the sliding-mode control. Recently, Time Delay Control (TDC) has also attracted attention as an excellent robust nonlinear control algorithm. The main purpose of using TDC methods is to assure control performances (such as accuracy, stability, speed, etc) Generally, TDC uses the time-delayed values of control inputs and derivatives of state variables at the previous time step to cancel the nominal nonlinear dynamics and the aforementioned uncertainties. Thus, TDC does not require any real-time computation of nonlinear dynamics, nor does it use the parameter estimations as in adaptive control [19].

Proportional integration (PI) controller is unquestionable as the most common controller in the process control industry. The main reason for using this controller is its relatively simple structure, which can be easily understood and implemented in practice. It also implemented in the sophisticated control strategies, such as model predictive control [20]. PI control is math total of integration error and multiplying of error with constant [21]. A simplest method to control the rotation speed of a DC motor is to control its driving voltage. The higher the voltage is the higher speed the motor tries to reach. In many applications, a simple voltage regulation would cause lots of power loss on control circuit, thus, a pulse width modulation method (PWM) is used in many DC motor controlling applications [4, 22]. In the basic PWM method, the operating power to the motors is turned ON and OFF to modulate the current to the motor. The PWM control method uses the widths of pulses in a pulse train to control the speed of the motor [23]. The pulses are arranged such that, only one pulse occurs for every period of the system clock. The duty cycle of the pulses determines the speed of the motor. Therefore, the higher the duty cycles the higher the speed [4]. This would give the motor the ability to safely vary the speed from stand still to its maximum speed. For this reason, the PWM method was chosen to be implemented in the motor control design. Sometimes, the rotation direction needs to be changed. In the normal permanent magnet motors, this rotation is changed by changing the

polarity of operating power (for example by switching from negative power supply to positive or by interchanging the power terminals going to power supply). This direction changing is typically implemented using relay or a circuit called an H bridge [3].

The main purpose of interfacing motor control is to implement a closed-loop control of servo motor position utilizing a local interconnect network (LIN) to allow a series of similar motors connected together and controlled by master controller. Since the motor is used for steering and driving systems, a single controller can be used for both functions. A microcontroller is applied to produce the PWM signal. The control programming based on computer interfacing to produce the PWM output would eliminate the need for additional hardware, saving on the overall cost of such a motor drive circuit [24, 25]. The Complex high-performance controllers such as PID have to be programmed and loaded into the microcontroller by converting it into hex file. Interfacing the motor with computer programming is achieved by the generated PWM signal from microcontroller. The control system on the hardware uses all the necessary features to meet the requirements of LIN applications [26, 27, 28].

3. Principle operation of dc servo motor control

Servos are controlled by a pulse of variable width. The sent signal of this input pulse is characterized by a minimum pulse, maximum, and a repetition rate as seen in Figure 1. Given the rotation constraints of the servo, neutral is defined to be the position where the servo has exactly the same amount of potential rotation in a clockwise direction as it is in a counter clockwise direction [29]. The angle is determined by the duration of applied pulse to the signal wire which is called PWM or Pulse Coded Modulation. The servo should detect a pulse every 20 ms. The length of the pulse will determine how far the motor turns. For example, a 1.5 ms pulse will make the motor turn to a 90 degree position (neutral position). The position pulse must be repeated to instruct the servo to stay in position [28].

Fig. 1: Input pulse of servo motor

When a pulse is sent to a servo that is less than 1.5 ms, the servo rotates to a position and holds its output shaft some number of degrees counter-clockwise from the neutral point. When the pulse is wider than 1.5 ms, the opposite operation is occurred. The minimal width and the maximum width of pulse that will command the servo to turn to a valid position are functions of each servo. Generally the minimum pulse will be about 1 ms wide (some servo is 0.5 ms) and the maximum pulse will be 2 ms wide (some servo is 2.5 ms). The servo motor operates in the range of 5 % to 10 % of duty cycles. Figure 2 shows relationship between pulse and direction of servo motor.

Fig. 2: Relationship between pulse and direction of servo motor

The PWM is a commonly used technique for controlling power into electrical device. The average value of voltage (and current) fed to the load is controlled by turning the switch between supply and load, ON and OFF at a fast pace. The longer the switch is ON compared to the OFF periods, the higher the power supplied to the load is. AC drives required the sinusoidal signal and modulation generator. The triangular signal is the carrier or switching frequency of the inverter. The modulation generator produces a sine wave signal that determines the width of the pulses, and therefore the RMS voltage output of the inverter. For DC drives, the PWM signal is generated by comparing a triangular wave signal with a DC signal as shown in Figure 3. The DC signal can be ranged between the minimum and maximum voltages of the triangle wave. The PWM signal is measured using the percentage of duty cycle where the pulse duration over the pulse period [26].

Fig. 3: The generation of PWM for DC drives

The mathematical model of DC servo motor can be simplified by mean of the circuit as shown in Figure 4. The electrical part represented by armature and the mechanical part by T and J. As the field excitation is constant, the armature controller only depends on armature voltage [30, 31]. The mechanical equations describing this system can be written with the

assumptions that the loss is included in load torque and neglecting viscous friction constant [30] as given below,

Fig. 4: DC servo motor equivalent circuit

$$V_a = R_a i + L_a \frac{di}{dt} + E_b \quad (1)$$

$$J \frac{d\omega}{dt} = T_e - T \quad (2)$$

With,

$$E_b = K \check{S} \quad (3)$$

$$T_e = K i \quad (4)$$

where, i : armature current; V_a : armature voltage; R_a : armature resistance; L_a : armature inductance; K : torque and back electromagnetic constant ($Nm.A^{-1}$); \check{S} ; rotor angular speed; T_e : electromagnetic torque; T : total load torque; J : rotor inertia.

The control input is the armature voltage V_a and the total load torque T is the disturbing input. The two state variables are armature current i and angular speed \check{S} . Then the previous equations lead to the state space model of DC motor:

$$\begin{bmatrix} \frac{di}{dt} \\ \frac{d\check{S}}{dt} \end{bmatrix} = \begin{bmatrix} -\frac{R_a}{L_a} & -\frac{K}{L_a} \\ \frac{K}{J} & 0 \end{bmatrix} \begin{bmatrix} i \\ \check{S} \end{bmatrix} + \begin{bmatrix} \frac{1}{L_a} & 0 \\ 0 & -\frac{1}{J} \end{bmatrix} \begin{bmatrix} V_a \\ T \end{bmatrix} \quad (5)$$

The two state variables excited the angular speed in order to perform a speed regulator related with the angular speed. Therefore, \check{S} is considered as the output of the system and V_a is the input. Taking into account only these two system variables, the transfer function of the DC motor is:

$$H(s) = \frac{\check{S}(s)}{V_a(s)} = \frac{1}{K} \frac{1}{\left(1 + \frac{R_a J}{K^2} s + \frac{L_a J}{K^2} s^2\right)} \quad (6)$$

The two time constants are defined as:

Electrical time constant,

$$\tau_e = \frac{L_a}{R_a} \quad (7)$$

And electro mechanical time constant,

$$\tau_{em} = \frac{R_a J}{K^2} \quad (8)$$

Therefore,

$$H(s) = \frac{\Omega(s)}{U(s)} = \frac{1}{K} \frac{1}{(1 + \tau_{em}s + \tau_{em}\tau_e s^2)} \quad (9)$$

4. Software implementation of servo motor control

This section presents the simulation procedures of servo motor control using the Proteus and Matlab software interfaced with Virtual Serial Port. The Proteus design suite is wholly unique in offering the ability to co-simulate both high and low-level microcontroller code in the context of a mixed-mode SPICE circuit simulation. There are over 8000 digital and analog devices model that can be simulated by placing and wired it up. The most exciting and important feature of Proteus is its ability to simulate the interaction between software running on a microcontroller and any analog or digital electronics connected to it. Proteus can work with popular compiler and assembler to simulate the execution of the object code (machine code), just like a real chip. If the program code is written to a port, the logic levels in the circuit will be changed accordingly, and if the circuit changes the state of the processor's pins, this can be seen by the program code, just as in a real life [32, 33].

The application of GUI for system control is widely used in the industries and robotic. In this work, the slider in Matlab GUI contributes to control the servo motor rotation angle as seen in Figure 5. The signal data obtained from the adjusted slider will be sent to the microcontroller and this signal will rotate the servo motor based on the desired angle adjusted by slider. The schematic diagram of servo motor control is shown in Figure 6. The system was built and developed using Proteus software incorporating with Matlab coding. The microcontroller coding are compiled using the Micro Code Studio. Hex file of coding program can be uploaded into the microcontroller to make it ready for real application during hardware implementation. As seen from Figure 7, the output from microcontroller is measured using the digital oscilloscope provided within Proteus. This measurement is an important to determine the correct output from the microcontroller into a servo motor. The Virtual Serial Port Kit creates virtual serial ports and connects each pair of them via a virtual null-modem cable. Consequently, all the data written to one virtual serial port can be immediately read by the other one, and vice versa. Moreover, this functionality is easily integrated into the software. Figure 8 shows how virtual null-modem cables are connected between two serial ports [32, 33]. The ports have to be defined correctly in virtual serial port to make sure that the signal has been sent into the right path.

Fig. 5: Servo motor control graphical user interface

Fig. 6: The schematic diagram of servo motor control

Fig. 7: Digital oscilloscope within Proteus

Fig. 8: Virtual Null-modem cables connection

In order to control the servo motor, the Matlab interfacing with Proteus software is achieved by the combination of GUI, microcontroller and virtual port communication between Matlab and Proteus as shown in Figure 9. The pair of serial ports is fixed at COM2 for GUI and COM4 for microcontroller as seen in Figure 10. The procedures of interfacing simulation are summarized below:

- Construct the schematic diagram using Proteus software.
- Write the PIC coding in Micro Code Studio compiler and compile them. This can be done using compiler such as MPLAB. The outcome of compiling is the generation the HEX file.
- Upload the HEX file to the microcontroller in the Proteus software.
- Run the Virtual Serial Port and define both ports; COM2 for Matlab and COM4 for serial port (COM-PIN) at the Proteus.
- Define the serial port (COM-PIN) at the Proteus as COM 4.
- Define the port at the m-file (the written program of servo motor control) of Matlab GUI as COM2.
- Run both software and start controlling the servo motor using sliders

Fig. 9: Virtual port communication

Fig. 10: The virtual interface between Matlab and Proteus

Referring to the whole controlling system, the servo controller receives position commands through a serial connection which can be provided by using one input/output (I/O) pin of another microcontroller, or a PC's serial port. This pulse signal will cause the shaft to locate itself at the midway position ± 90 degrees. The shaft rotation on a servo motor is limited to approximately 180 degrees (± 90 degrees from center position). A 1-ms pulse will rotate the shaft all the way to the left, while a 2-ms pulse will turn the shaft all the way to the right. By varying the pulse width between 1 and 2 ms, the servo motor shaft can be rotated to any degree position within its range.

5. Hardware implementation of servo motor control

Figure 11 shows the schematic diagram of the controlling system, and the hardware of this system is depicted in Figure 12. The application of MAX232 is used to regulate the signal from PC to microcontroller during the interfacing process. The chip receives signals -10V to +10V from PC for logic '0' and '1' and converts them into 0V and 5V in logic '0' and '1' for microcontroller in order to process the sending data. Serial port acts as a medium for sending the data from PC to servo motor control circuit. This controlling system is using the Integrated Circuit (IC) LM 7805 to regulate the 5V voltage supply to entire circuit. A light-emitting diode (LED) is used as an indicator to determine the PWM output generated by microcontroller and sent to the servo motor. The DC servo motor utilized in this hardware is a Cytron RC Servo motor (C40R). The specification of this motor is given in Table 1 [31]. PIC16F628A is the selected microcontroller chip to control the speed of DC servo [25].

RS-232 is a standard for serial binary data signals connected between data terminal equipment and data circuit terminating equipment [32]. According to this standard a logical "0" has a voltage level between -15V and -5V and a logical "1" has a level between +5V and +15V. The microcontrollers use a 5V TTL-level (transistor-transistor logic) to transmit signals. Therefore, the signals should be converted by using MAX232 that only needs a 5V power supply to convert the signal from TTL-level to RS232 level and reverse. RS232 is a serial interface that transfers the data bit by bit and requires only two single wires, one, to send and another, to receive the data. Most of digital logic circuits and processors operate with a "+5" volt. Usually the input circuit is unregulated power supply ranging from 9 volts to 24 volts (DC). For this reason, LM 7805 is placed in the hardware and reacts as a regulator to supply +5 volt [33].

Input voltage (V)	5

The rotational angle of DC servo motor is measured manually using the protractor. One of the blades will be marked as a reference point. The DC motor is placed at the centre of the protractor and each movement of the slider in GUI Matlab will rotate the servo motor and the angle can be recorded. Figure 13 illustrates the measurement of angle, the maximum and minimum values of angle in the slider are in the range of 0° to 180°. The angle must be limited to 180°. For example, if the slider has a range of 90° to -60°, it means that the measured value by the instrument in the range of maximum and minimum is 150°.

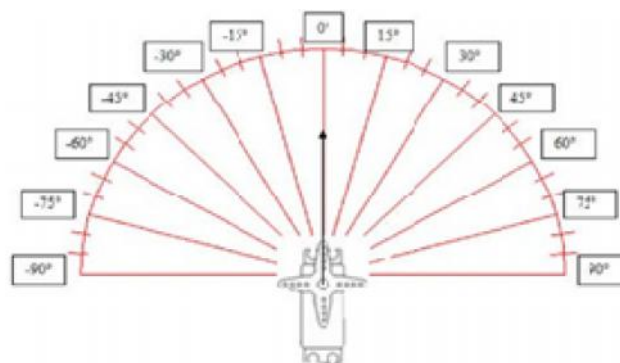

Fig. 13: Angle measurement

6. Result and discussion

The simulation is used to validate the results obtained from Proteus interfacing with Matlab GUI and with those found by the hardware interfacing in Matlab GUI. The GUI is manually controlling the desired rotation angle of servo motor by the slider. Figure 14

shows the 90° rotation of servo motor indicated by slider and the input signal from the PC into the microcontroller. Table 2 illustrates the measurement values of five motors taken during the simulation.

Fig. 14: Servo motor 1 at 90° and the input signal from PC

Table 2: The measurement values of five motors taken during the simulation

Servo Motor	Slider Position (°)	Servo angle (°)	PWM output (ms)	Voltage Magnitude PWM output (V)	Sending signal from PC(mV)
1	90	90	2.35	2.54	214.52
	-30	-30	1.10	2.55	267.91
2	-60	-60	0.80	2.58	290.07
	80	80	1.95	2.52	300.09

	240	240	2.80	2.56	177.64
	170	170	1.65	2.57	302.42

For real time implementation, the measurements of input signals and PWM output from the microcontroller were recorded in order to be compared with the signals obtained by the simulation. Figure 15 shows the real time implementation of the hardware. The initial measurement of the input (7.20 mV) and output signal (161 mV) are shown in Figure 16. Table 3 illustrates the measurement values of five motors taken during the hardware testing.

Fig. 15: Real time hardware testing

Fig. 16: Sending signal from PC and output from the microcontroller

As seen from the software and hardware results, the system is not operating as desired for some sent signals from the PC into the control circuit. The measurement of signals from the PC is too small and these signals cannot be operated by the microcontroller. But, the circuit and GUI are functioning well in terms of rotating angle. The hardware results show that the output signals from microcontroller with a shape approaching the sine wave form. On the other hand, the outputs of microcontroller supposed to be as square wave and exceeding the PWM shape for DC drive. Finally, a comparison results between the simulation and real-time implementation are given in Table 4. As noted from the table, the values of the simulated and real time signals are not similar. The functions of the virtual

interface and the database system may need to be expanded to meet the different types of PC configurations to perform an accurate sending of signals into the hardware without loss of information. The compatibility of Matlab and Proteus, however, has an influence under the present condition.

Table 3: The measurement values of five motors

Servo Motor	Slider Position (°)	PWM output (ns)	Voltage Magnitude PWM output (mV)	Sending signal from PC (mV)

7. Conclusion

In this paper, microcontroller in Matlab GUI is proposed to control the desired position of rotation angle using the GUI sliders. Based on the regulated values, the sliders control the rotation of the servo motor. In real-time application, the sent data from PC is too small and the microcontrollers are not passing enough signals to produce the actual desired rotations. In order to improve the accuracy for real-time application, there is a need add amplifier for increasing the signals from PC to the microcontroller. The major contribution of this paper is the incorporation of two different softwares coding for real time control of a servo motor rotation angle using GUI in Matlab.
