Flux pinning and vortex transitions in doped BaFe2As2 single crystals

Abstract
The vortex liquid-to-glass transition has been studied in Ba$_{0.72}$K$_{0.28}$Fe$_2$As$_2$ (BaK-122), Ba(Fe$_{0.91}$Co$_{0.09}$)$_2$As$_2$ (BaCo-122), and Ba(Fe$_{0.95}$Ni$_{0.05}$)$_2$As$_2$ (BaNi-122) single crystal with superconducting transition temperature, $T_c=31.7$, 17.3, and 18 K, respectively, by magnetoresistance measurements. For temperatures below $T_c$, the resistivity curves were measured in magnetic fields within the range of $0 \leq B \leq 13$ T, and the pinning potential was scaled according to a modified model for vortex liquid resistivity. Good scaling of the resistivity $q(B, T)$ and the effective pinning energy $U_0(B,T)$ were obtained. The vortex state is three-dimensional at temperatures lower than a characteristic temperature $T^*$. The vortex phase diagram was determined based on the evolution of the vortex-glass transition temperature $T_g$ with magnetic field and the upper critical field, $H_{c2}$. We found that non-magnetic K doping results in a high glass line close to the $H_{c2}$, while magnetic Ni and Co doping causes a low glass line which is far away from the $H_{c2}$. Our results suggest that non-magnetic induced disorder is more favourable for enhancement of pinning strength compared to magnetic induced disorder. Our results show that the pinning potential is responsible for the difference in the glass states.

(Received 30 October 2011; accepted 30 January 2012; published online 17 February 2012)

The vortex liquid-to-glass transition has been studied in Ba$_{0.72}$K$_{0.28}$Fe$_2$As$_2$ (BaK-122), Ba(Fe$_{0.95}$Co$_{0.05}$)$_2$As$_2$ (BaCo-122), and Ba(Fe$_{0.95}$Ni$_{0.05}$)$_2$As$_2$ (BaNi-122) single crystal with superconducting transition temperature, $T_c = 31.7$, 17.3, and 18 K, respectively, by magnetoresistance measurements. For temperatures below $T_c$, the resistivity curves were measured in magnetic fields within the range of $0 \leq B \leq 13$ T, and the pinning potential was scaled according to a modified model for vortex liquid resistivity. Good scaling of the resistivity $\rho(B,T)$ and the effective pinning energy $U_0(B,T)$ were obtained. The vortex state is three-dimensional at temperatures lower than a characteristic temperature $T^*$. The vortex phase diagram was determined based on the evolution of the vortex-glass transition temperature $T_g$ with magnetic field and the upper critical field, $H_{c2}$. We found that non-magnetic K doping results in a high glass line close to the $H_{c2}$, while magnetic Ni and Co doping causes a low glass line which is far away from the $H_{c2}$. Our results suggest that non-magnetic induced disorder is more favourable for enhancement of pinning strength compared to magnetic induced disorder. Our results show that the pinning potential is responsible for the difference in the glass states. © 2012 American Institute of Physics. [doi:10.1063/1.3685507]

In the mixed states of type II superconductors, vortices form the Abrikosov lattice as a result of quantization of magnetic flux. Depending on the magnetic field, the vortex lattice can change from the solid to the glass state and will further transform to a liquid state and disappear at $H > H_{c2}$, where $H_{c2}$ is the upper critical field. The boundary between the lattice and glass or the glass and liquid phases is strongly affected by both the anisotropy and the disorder of a superconductor. The vortex glass line can be significantly suppressed in highly anisotropic superconductors such as high temperature superconductors, as the anisotropy is only around 2–3 in 122 compounds. In this work, the vortex liquid-to-glass transition has been studied in Ba$_{0.72}$K$_{0.28}$Fe$_2$As$_2$ (BaK-122), Ba(Fe$_{0.95}$Co$_{0.05}$)$_2$As$_2$ (BaCo-122), and Ba(Fe$_{0.95}$Ni$_{0.05}$)$_2$As$_2$ (BaNi-122) single crystal with $T_c = 31.7$, 17.3, and 18 K, respectively, by magnetoresistance measurements. We found that non-magnetic K doping results in a high glass line close to the $H_{c2}$, while magnetic Ni and Co doping causes a low glass line which is far away from the $H_{c2}$. Our results suggest that non-magnetic induced disorder is more favourable for enhancement of pinning strength compared to magnetic induced disorder.

The phase transition can be clearly visualized through the difference in resistive behaviour between the solid and liquid phases. The broadening of the resistivity transition in magnetic field is a direct consequence of the thermal fluctuation in the vortex system. Therefore, resistive transport measurements are commonly used to study vortices and vortex phase transitions. The vortex phase transition in cuprate superconductors can be understood using vortex-glass theory. According to this theory, in the vortex glass state and close to the glass transition temperature $T_g$, the resistivity decreases as a power law

$$\rho = \rho_0 \left( \frac{T}{T_g} \right)^{-f},$$

where $f$ is the power law exponent.

where $s$ is a constant related to the various types of disorder, which can be introduced by columnar defects, point defects, dopants, and vacancies. $\rho_{0}$ is the characteristic resistivity of the normal state. Equation (1) can be modified by using the energy difference $k_{B}T-U_{0}$, where $U_{0}$ is the effective pinning energy. Therefore, the driving force of the transition depends on the energy difference, instead of the temperature difference of $T-T_{g}$. Therefore, Eq. (1) is re-formulated as

$$\rho = \rho_{n} \left| \frac{k_{B}T}{U_{0}(B,T)} - 1 \right|^s. \quad \text{(2)}$$

Here $\rho_{n}$ is the normal state resistivity at the onset of the transition. In this model, the vortex solid to vortex liquid transition occurs when the two energy scales are equal, $U_{0}(B,T_{g}) = k_{B}T_{g}$. An empirical effective pinning energy was found

$$U_{0}(B,T) = U_{B} \left( 1 - \frac{T}{T_{c}} \right) \text{ with } U_{B} = k_{B}T_{c}/(B/B_{0})^\beta,$$

where both $B_{0}$, which is inversely proportional to the square of the mass anisotropy, and $\beta$ are temperature and field-independent constants. By considering the effective pinning energy at the glass temperature, i.e., $U_{0}(B,T_{g}) = k_{B}T_{g}$, the temperature dependent vortex glass line is obtained from \cite{10,11}

$$B_{g}(T) = B_{0} \left( 1 - \frac{T}{T_{c}} \right)^{1/\beta}. \quad \text{(4)}$$

This has been used to determine the vortex glass for Y-123. \cite{10–13}

A useful scaling form for resistivity was obtained by combination of Eqs. (2) and (3)

$$\rho = \rho_{n} \left| \frac{T(T_{c} - T)}{T_{g}(T_{c} - T_{g})} - 1 \right|^s. \quad \text{(5)}$$

Therefore, the resistivity in the vortex glass state depends on magnetic field through $T_{g}$. Although Strachan et al. \cite{15} suggested that agreement with scaling alone does not prove the existence of a phase transition, but experimental evidence for the vortex-glass phase has been obtained for various high-$T_{c}$ superconductors such as Y-123, \cite{10–12} TI-2212, \cite{13,14} MgB$_2$, \cite{16} and Ba$_{0.55}$K$_{0.45}$Fe$_2$As$_2$ (Ref. 17) through the scaling exponent, as predicted by vortex–glass and modified vortex–glass theory. However, the vortex-glass phase transition and scaling behaviour have not been investigated systematically in detail in the Fe-based superconductors.

Here, we have studied the glass transition from the vortex liquid side in BaK-122, BaCo-122, and BaNi-122 single crystal by magnetoresistance measurements. Good scaling of the $\rho(B,T)$ and $U_{g}(B,T)$ was obtained with the critical exponents $s$ for all crystals. The vortex phase diagram was determined based on the evolution of the vortex-glass transition temperature $T_{g}$ with magnetic field and the upper critical field. We have also compared the modified vortex-glass model and the thermally activated flux flow model in the vortex liquid region.
H//c, is shown in the Arrhenius plot in inset Fig. 2. The transition temperatures, Tc, are 31.7, 17.3, and 18.0 K, with almost the same small transition width (ΔTc) of 0.7 ± 0.1 K for BaK-122, BaCo-122, and BaNi-122 single crystals, respectively.

Equation (5) suggests a scaling behaviour of the vortex glass between the normalized resistivity ρ/ρ0 and the scaled temperature Tsc = [T (Tc − Tg)/Tg]1/2 − 1. Figure 2 shows the ρ/ρ0 versus scaling temperature Tsc. As can be seen in Fig. 2, the resistivity transition at fields between 0 and 13 T has been scaled into one curve with the obtained critical exponent Vortex glass with the same resistivity scaling behaviour has been observed in several high-Tc superconductors such as oxygen-deficient Y-123 single crystal11,12 and TI-2212 thin film.13

The upper critical field, Bc2, is obtained from the 90% values of its corresponding resistivity transition. Using the estimated vortex glass line Bg, the B-T phase diagram for the BaK-122, BaCo-122, and BaNi-122 single crystals is shown in Fig. 3. According to the collective pinning model,20 the disorder-induced spatial fluctuations in the solid-vortex lattice can be clearly divided into markedly different regimes according to the strength of the applied field. As is shown in the inset of Fig. 3, two different regimes are distinguishable: (1) vortex glass, which governs the region below Bg; (2) vortex liquid, which holds between Bg and Bc2, where thermal fluctuations are important. As can be seen from Fig. 3, the vortex-glass phase indicates that the K doped BaFe2As2 single crystal has a very narrow region of the vortex-liquid phase, which is denoted by ΔT in the inset of Fig. 3, with a small ΔT of 0.06 ± 0.02 T and at magnetic field of 0.5 up to 13 T (weakly field dependent), which has originated from the vastly enhanced vortex pinning. However, the glass lines for both Co (ΔT = 0.18 ± 0.02) and Ni doped 122 single crystals are far from the Hc2 lines and strongly temperature dependent for Ni122 (ΔT = 0.03–0.22 for the B = 0.5–13 T range). This indicates that the vortex liquid state exists in a wide range of fields below Hc2. This is significantly different from BaK-122. The Co and Ni (magnetic doping) shifts the vortex-glass transition to lower temperature or softening vortex lattice as compared to K (non-magnetic doping). The magnetic doping was decreased Tc and the slope of the mean field normal phase-mixed phase boundary line, dHc2/dT |Tc−Tc, as seen in Figs. 2 and 3. The smaller change of coherence length (ξ = (φ0/2πHc2)1/2, φ0 is the flux quanta) by non-magnetic doping relative to magnetic doping implies some possible vortex-impurity interactions causing an enhanced pinning or stiffening of the vortex system and bring about the transition to the vortex-solid phase at higher temperature. This is supported by higher pinning potential for K doping than that for Co and Ni as will be discussed later. As Ni and Co substitute Fe sites, it can induce distortion or imperfection to the FeAs planes compared to the K doping which can mainly provide more charge carries, but cause little changes to the FeAs planes. It seems that the distortion of FeAs plane is likely associated with pinning and Tc. A further study is needed to elucidate the origin of the differences of the pinning in non-magnetic K and magnetic Ni and Co ion doped 122 crystals. Another important point is that one can directly observed that ΔT of BaK-122 is smaller than for BaCo-122 or BaNi-122, which is an indication that the pinning potential of BaK-122 is stronger than for either BaCo-122 or BaNi-122 single crystals. This is supported by the pinning potential results, as can be seen in Fig. 5. The results show that non-magnetic doping, such as K on Ba site, and magnetic doping, such as Co or Ni on the Fe site, have different effects on the vortex glass line. The question is what the effect will be on the vortex glass line of magnetic and non-magnetic substitution on the same site, especially the Fe site, which is located on the FeAs plane. This requires further study.

FIG. 3. (Color online) Phase diagrams of BaK-122 (squares), BaCo-122 (stars), and BaNi-122 (circles) single crystals. Bg was obtained from the experimental ρ(T) and U0(T) data (see Figs. 2 and 4). Bg(T) values were obtained from the criterion of the 90% values of their corresponding resistivity transition. Open symbols: Bg; and solid symbols: Bg. Inset: general phase diagram.

FIG. 4. (Color online) The pinning potential U0(B,T) as calculated according to Eq. (6) in field of 0 ≤ H ≤ 13 T for (a) BaK-122, (b) BaCo-122, and (c) BaNi-122 single crystal.
By solving Eq. (2) for $U_0$, one obtains

$$U_0(B,T) = k_B T \left[ 1 + \left( \frac{\rho_n}{\rho_n^0} \right)^{1/s} \right]^{-1}. \quad (6)$$

According to Eq. (6), the pinning potential can be calculated directly from experimental data, provided that one knows the $\rho_n$ and the exponent $s$. The $s$ parameter is estimated as the inverse slope of the resistivity in the vortex glass state, as mentioned above, and the $\rho_n$ has been taken as the normal state resistivity at $T = 35$ K for BaK-122 and $T = 20$ K for both BaCo-122 and BaNi-122 single crystals. The calculated $U_0(B,T)$ of the BaK-122, BaCo-122, and BaNi-122 single crystals for fields between 0 and $13$ T is shown in Fig. 4. As can be seen in the solid lines, the low resistivity of the curves is well described by Eq. (3) with a field dependent $U_B$.

As can be seen in Fig. 4, an extrapolation of the linear behaviour of $U_0(T)$ at temperatures close to $T_g$ and at different fields merges in the point $T = T_g$ and $U_0 = 0$ which is in good agreement with Eq. (3). Therefore, the field dependence of the pinning energy $U_B$ can be found directly from the slope of these lines. The magnetic dependence of the estimated result from Fig. 4 for $U_B$ is shown in Fig. 5. As can be seen in Fig. 5, the pinning potential of BaK-122 single crystal is constant, while different power law dependence is found for low and high magnetic fields for both BaCo-122, and BaNi-122 single crystal. The $U_B/k_B$ decreases slowly with increasing applied magnetic field for $B > 3$ T, scaled as $B^{-0.06}$, and then decreases as $B^{-0.9}$ for $B > 3$ T. This result suggests that the single vortex pinning may co-exist with collective creep in low fields and then the collective creep dominates in high magnetic fields.

Another important point is that one can directly obtain $T_g$ by considering the crossing points of the lines $U_0(B,T)$ and the line $U_0 = k_B T_g$, as indicated by the arrows in Fig. 4. This criterion was used for estimating $T_g$ in the modified vortex-glass model. Therefore, $U(B,T)$ is the average pinning energy in the system and is responsible for the vortex solid to liquid transition when $U(B,T_g) = k_B T_g$, as discussed in the Introduction.

In many studies, the vortex liquid resistivity is described by a thermally activated flux flow (TAFF) model, $\rho(T, H) = \rho_n \exp (U^*/k_B T)$, where $\rho_n$ is the normal state resistivity and $k_B$ is the Boltzmann constant. By using the TAFF model, we obtained the activation energy, $U^*/k_B = \partial \ln \rho_0 / \partial (1/T)$, which is shown in the inset of Fig. 5. At $B = 1$ T, $U^*/k_B$ was 6400, 3311, and 1626 K for the BaK-122, BaCo-122, and BaNi-122 single crystals, respectively, while $U_B/k_B$ was 192, 77, and 32 K. Although $U^*$ is larger than $U_B$ in value, it has a similar magnetic field dependence. For comparison of these values, by taking the derivative $\partial \ln \rho_0 / \partial (1/T)$ of Eq. (2) and using Eq. (3), one can obtain the relation $U^* = \frac{(1 + (\rho_n/\rho_n^0))^{1/s}}{(\rho_n/\rho_n^0)^{1/s}} U_B = A U_B$. By using $s$ and experimental data of $\rho/n_s \approx 10^{-1} \sim 10^{-2}$, the correction factor $A$ is between $24-33$, 21-32, and 20-28 for the BaK-122, BaCo-122, and BaNi-122 single crystals, respectively. Therefore, there is an excellent agreement between both models.

In conclusion, it was shown that the glass transition introduced based on a modified model for the vortex-glass transition can be applied to the doped BaFe$_2$As$_2$ superconductors. For temperature below the superconducting transition temperature, a scaling of all measured resistivity $\rho(B, T)$ and pinning potential $U_0(B,T)$ values in magnetic fields up to $13$ T with the critical exponents $s$ is obtained. The vortex phase diagram was determined based on the evolution of the vortex-glass transition temperature $T_g$ with magnetic field and the upper critical field. The results suggest that the vortex region of BaK-122 is shorter than it is for BaCo-122 and BaNi-122, and it is also magnetic field independent in magnetic fields smaller than $13$ T. It was found that the pinning force of BaK-122 is stronger than for BaCo-122 and BaNi-122. Furthermore, we compared these results with the thermally activated flux flow behaviour which is usually employed to account for the resistivity in the vortex liquid region.
