Hollow carbon spheres with encapsulated germanium as an anode material for lithium ion batteries

Abstract
A novel composite consisting of hollow carbon spheres with encapsulated germanium (Ge@HCS) was synthesized by introducing a germanium precursor into the porous-structured hollow carbon spheres. The carbon spheres not only function as a scaffold to hold the germanium and thus maintain the structural integrity of the composite, but also increase the electrical conductivity. The voids and vacancies that are formed after the reduction of germanium dioxide to germanium provide free space for accommodating the volume changes during discharging-charging processes, thus preventing pulverization. The obtained Ge@HCS composite exhibits excellent lithium storage performance, as revealed by electrochemical evaluation.

1. Introduction

The increasing demand for clean and green energy is currently shifting towards alternative energy sources such as wind power, tidal power, solar cells, fuel cells, and batteries [1]. Lithium ion batteries have been considered to be the most promising energy storage system for portable electrical devices, electric vehicles, hybrid electric vehicles, etc [2]. Lithium ion batteries are more suitable for such purposes compared to previous conventional batteries, including metal hydride, alkaline, and lead-acid batteries, due to their high power density and high energy density. To further satisfy the demand, much research has been recently focused on high capacity materials. Group IVA materials have attracted significant interest as anode materials for lithium ion batteries due to their high theoretical capacity, especially silicon and germanium, which exhibit high theoretical capacities of 4200 mA h g\(^{-1}\) and 1623 mA h g\(^{-1}\) (4.4 Li\(^+\) per silicon or germanium atom), respectively [3-5]. In the case of silicon, its practical use in commercial application is limited by inferior cycling performance because of the great volume changes during cycling and the poor rate capability caused by its inherent low ionic diffusivity and electronic conductivity. Compared to silicon, germanium can boost the electrical conductivity to two orders of magnitude higher, and the lithium diffusivity to four orders of magnitude faster [3, 6]. Furthermore, it has been proved that the total system energy can be dramatically decreased by the high adsorption energy of lithium ions on the germanium surface [5]. These outstanding properties make germanium an excellent candidate anode material for lithium ion batteries. Like silicon, however, the major drawback of germanium is the large volume change during lithiation/de-lithiation processes, which results in cracking, pulverization, and loss of electrode contact, leading to poor cyclability and capacity fading [7]. Synthesis of nanostructured morphologies, such as nanowires [4, 7-9], nanotubes [5, 10], and nanoparticles [11], is an effective method to address this issue by accommodating the volume change, introducing relaxation mechanisms
to tolerate strain, and alleviating the pulverization. Another significant strategy is developing a carbon-based germanium composite that not only provides a volume expansion buffer for lithium ion intercalation, but also improves the electrical conductivity of the material. There are many previous studies that have reported germanium modified by various carbon sources, for example, nanostructured germanium interconnected by carbon synthesized by a reduction reaction between amorphous GeO$_2$ and carbon [12], single crystalline germanium nanowires sheathed with carbon prepared by a solid-liquid solution method [4], self-assembled germanium-carbon nanostructures obtained through carbon coating and reduction of the oxide precursor [11], carbon covered germanium particles embedded into reduced graphene oxide networks [13], sandwich-structured C/Ge/graphene composite synthesized by a microwave-assisted solvothermal reaction and then carbon-coating the surface of the germanium/graphene precursor [14]. Hollow carbon spheres (HCS) have attracted considerable attention because of their promising applications in catalysis, lithium-ion batteries, fuel cells, supercapacitors, and water treatment [15, 16]. Resorcinol-formaldehyde resin (RF) is considered as one of the most fascinating and versatile carbon precursors for the designed synthesis of HCS [17]. Moreover, it is reported that hexadecyltrimethylammonium bromide (CTAB) modified HCS are endowed with a uniform microporous structure with superior surface properties, which could be beneficial to the introduction of metal precursors. Therefore, their unique structure makes HCS a good candidate for synthesizing a composite with germanium encapsulated in carbon spheres.

Herein, hollow carbon spheres were firstly synthesized using silicon spheres as hard templates. The carbon spheres were modified by CTAB in the process of RF coating to obtain a porous structure, which not only increases the contact area between the electrode and electrolyte, but also facilitates the introduction of the germanium precursor. Within this architecture, the germanium can freely undergo lithiation/de-lithiation processes without agglomeration due to the protecting scaffold effect of the carbon spheres and the voids that
are formed after the reduction treatment of the precursor, thus securing the structural and
electrical integrity of the electrode during repeated cycling. This unique encapsulation of
germanium in hollow carbon spheres endows the obtained materials with enhanced
electrochemical properties.

2. Experimental Section

Synthesis of SiO$_2$ spheres: SiO$_2$ spheres were synthesized by a slightly modified Stöber
process [18]. In a typical synthesis, 0.6 mL tetraethyl orthosilicate (TEOS) was added into a
mixture of 63.3 mL isopropyl alcohol, 23.5 mL deionized water, and 13.0 mL ammonium
aqueous solution (30%), and then vigorous stirred at room temperature for 1 h. Then, 5 mL
TEOS was added dropwise into the solution at 35 °C for 2 h. Then, the SiO$_2$ spheres were
centrifugally separated from the suspension and washed with ethanol and deionized water five
times before drying in a vacuum oven at 70 °C overnight.

Synthesis of SiO$_2$@RF core-shell spheres: 1 g of the obtained SiO$_2$ spheres was
homogeneously dispersed in a solution of deionized water (70 mL) and ethanol (28 mL) by
ultrasonication for 30 min, followed by the addition of 2.3 g hexadecyl trimethyl ammonium
bromide (CTAB), 0.35 g resorcinol, and 0.1 mL ammonium aqueous solution, and then
stirring at room temperature. The mixed solution was homogenized for 30 min to form a
uniform dispersion. Then, 0.5 mL formaldehyde solution was added to the dispersion with
continuous stirring for 8 h at 35 °C. After that, the products, the SiO$_2$@RF core-shell spheres,
were collected by centrifugation and washed with ethanol and deionized water five times
before drying in a vacuum oven at 70 °C overnight.

Synthesis of hollow carbon spheres (HCS): The as-prepared SiO$_2$@RF core-shell spheres
were carbonized under argon atmosphere at 350 °C for 1.5 h, followed by a further annealing
treatment at 900 °C for 3 h with a heating rate of 1 °C min$^{-1}$. Finally, the furnace was left to
cool down to room temperature before the obtained SiO$_2$@C spheres were removed from the
After soaking and washing in 3 M NaOH aqueous solution at 70 °C for 48 h, the as-synthesized SiO₂@C core-shell spheres were converted into HCS.

_Synthesis of GeO₂@hollow carbon spheres (GeO₂@HCS):_ 0.5 g HCS was sealed in a two-neck flask, which was then subjected to vacuum for 30 min. Then, 1.5 g germanium ethoxide was injected into the evacuated flask, stirred for 48 h, and washed with ethanol two times to remove extra germanium ethoxide before drying in a vacuum oven at 70 °C overnight.

_Synthesis of Ge@hollow carbon spheres (Ge@HCS):_ The as-prepared GeO₂@HCS sample was reduced to Ge@HCS under 5% hydrogen/argon gas at 650 °C for 10 h with a heating rate of 5 °C min⁻¹.

_Synthesis of GeO₂ bulks, GeO₂@carbon bulks (GeO₂@C bulks), and Ge@carbon particles (Ge@C particles):_ GeO₂ bulks were obtained by the natural hydrolysis of germanium ethoxide in a sealed vial for 48 h. Then, the obtained GeO₂ bulks were coated with a carbon layer through carbonization in ethanol vapour in nitrogen at 650 °C for 3 h with a heating rate of 5 °C min⁻¹ to obtain the GeO₂@C bulks. The Ge@C particles were synthesized by reducing the as-prepared GeO₂@C bulks under 5% hydrogen/argon gas at 650 °C for 10 h with a heating rate of 5 °C min⁻¹.

_Characterization:_ The crystalline phases of the resultant materials were analysed by powder X-ray diffraction (XRD, MMA GBC, Australia), which was carried out using Cu Kα radiation (λ = 1.54056 Å) from 2θ = 10° to 80°. The morphologies and structures of the samples were characterized by field-emission scanning electron microscopy (SEM, JSM-7500FA, JEOL, Japan), and transmission electron microscopy (TEM) investigations were performed using a JEOL 2011F analytical electron microscope (JEOL, Japan) operating at 200 keV. Raman spectroscopy was used to characterize the germanium and carbon using 514 nm laser excitation. Thermogravimetric analysis (TGA) was carried out to determine the carbon content with a TGA/differential scanning calorimetry (DSC) type instrument (METTLER
TOLEDO, Switzerland) at a heating rate of 10 °C min⁻¹ from room temperature to 800 °C in air.

**Electrochemical Measurements:** To prepare the working electrode for electrochemical testing, an electrode slurry of Ge@HCS was prepared by thoroughly mixing the active material, polyacrylic acid, sodium carboxymethyl cellulose, and acetylene black in a weight ratio of 80:5:5:10 in de-ionized water. For the Ge@C particle sample, the slurry was made up in a weight ratio of 83.2:4.2:4.2:8.4 in order to keep the same carbon content as in the Ge@HCS electrode. The resultant slurries were then spread onto copper foil substrates and dried in a vacuum oven at 150 °C for 3 h. The electrochemical tests were carried out with CR2032 coin type cells, which were assembled in an argon-filled glove box (Mbraun, Unilab, Germany). The cells were constructed of the prepared active material on copper substrate as cathode, microporous polyethylene (Celgard 2400) as the separator, lithium foil as anode, and 1.15 M LiPF₆ in a ethylene carbonate (EC)/dimethyl carbonate (DMC)/diethyl carbonate (DEC) (3:4:3 by volume) as the electrolyte. The charge/discharge cycling was performed within the voltage range of 0.01-1.5 V vs. Li⁺/Li on a battery test instrument (CT2001A, KINGNUO, China) at ambient temperature. The loading amount of active material for all electrodes was at least 0.9 mg cm⁻². The specific capacities were calculated based on the weight of the composites.

3. Results and Discussion

Figure 1 illustrates the general route to synthesize the Ge@HCS composite through introducing germanium ethoxide into the hollow carbon spheres, followed by a thermal reduction treatment. In a typical synthetic procedure, the SiO₂ template spheres are synthesized by a modified Stöber method and then covered with a uniformed carbon layer transformed from carbonization of the self-assembled RF and CTAB. After etching with NaOH, the hollow carbon spheres are formed. It is noteworthy that the participation of the
cationic surfactant CTAB plays a significant role in the surface properties of the silica templates. The cationic CTAB can decorate the spheres with positive charges by forming a bilayer structure, which can easily make the negatively charged RF form a coating on the negatively charged Stöber silica spheres [19], promoting the following self-assembly of CTAB and RF on the silica sphere surfaces to form a polymer shell. Importantly, the CTAB modified polymer shells can be transformed to uniform microporous carbon spheres because of the elimination of CTAB after the carbonization treatment [20]. Therefore, the structure features carbon spheres equipped with high dispersibility and discreteness [21], which can have an affinity with the germanium ethoxide and thus allow it to penetrate the carbon layer and go into the center of a hollow carbon sphere under vacuum conditions. After a long stirring over 2 days, the vacuum beaker is gradually filled with air to ensure that the germanium ethoxide is hydrolyzed to Ge(OH)₄ and then converted to GeO₂. The obtained GeO₂@HCS undergoes a thermal reduction treatment and is finally transformed to Ge@HCS.

Figure S1 and Figure 1(a) contain SEM images of the SiO₂ templates, which consist of relatively monodisperse nanospheres about 250 nm in size. After the coating with RF resin and the following carbonization treatment, the hollow carbon spheres were obtained, which kept their uniform and monodisperse structure, as can be observed in the SEM and TEM images in Figure S2. Germanium ethoxide was introduced into the carbon spheres under vacuum and converted to GeO₂ after a long stirring process to facilitate a complete hydrolysis and oxidation reaction. The vacuum strategy is effective for loading the germanium precursor, which can be proved from the TEM image shown in Figure 2(b), indicating that the hollow centers of the HCS were fully occupied by GeO₂. SEM images of GeO₂@HCS are shown in Figure S3. After completion of the thermal reduction process, relatively thinner areas appeared inside the carbon spheres, which were stems from the produced voids and pores due to the release of oxygen when GeO₂ was reduced to elemental germanium (See Figure 2(c)).
From the SEM images (as shown in Figure S4), it can be found from broken carbon spheres that there are germanium particles inside the carbon spheres. Energy dispersive X-ray spectroscopy (EDS) gives further evidence to confirm the presence of germanium in the Ge@HCS sample in Figure S5. On the other hand, GeO\textsubscript{2}@C particles were synthesized for comparison by natural hydrolysis of the germanium ethoxide precursor without the presence of HCS under the identical synthesis conditions as those for the GeO\textsubscript{2}@HCS sample. The as-prepared GeO\textsubscript{2} bulks (shown in Figure S6) were transformed to GeO\textsubscript{2}/C bulks after the carbon-coating treatment, and then were further transformed to Ge@C particles after the thermal reduction process. Images of the morphology of the GeO\textsubscript{2}/C bulks and Ge@C particles are shown in Figures S7 and S8, respectively. X-ray diffraction (XRD) was applied to characterize the crystal structures of the obtained GeO\textsubscript{2}@HCS and Ge@HCS samples, as shown in Figure 2(d). All the reflection peaks of the GeO\textsubscript{2}@HCS are well indexed to the hexagonal phase of GeO\textsubscript{2} (JCPDS card No. 36-1463). The hexagonal phase is converted to diamond cubic phase (Ge) (JCPDS card No. 40-0545) after the reduction treatment. No peaks corresponding to carbon were detected in the pattern, which could be attributed to their overlapping with the (111) peak of germanium at around 27\(^\circ\). Further structural information is provided by the Raman spectra, as shown in Figure S9. The peak located at 294 cm\(^{-1}\) is attributed to the optical mode of crystalline germanium. Moreover, there is a strong D band at 1345 cm\(^{-1}\) indicating the presence of defects, and a G band at 1605 cm\(^{-1}\) that is attributable to the E\textsubscript{2g} vibrational mode for the \(sp^3\) domain [22]. The carbon content of the Ge@C particles and Ge@HCS composites was determined by thermogravimetric analysis (TGA), with the results shown in Figure S10. The calculated values are 11.9 wt\% and 10.3 wt\%, respectively.

The hollow carbon spheres encapsulating germanium with structural stability can offer excellent lithium storage performance, and the results are shown in Figure 3. For comparison, the cycling performances of Ge@C particles and Ge@HCS electrode are exhibited in Figure
3(a) up to 100 cycles at the rate of 0.4 C. The current density for the 1 C rate is 1600 mA g⁻¹. The Ge@HCS electrode delivers a significantly high specific capacity of about 1455 mA h g⁻¹ at the first cycle, corresponding to the quite high specific capacity of 1617 mA h g⁻¹ for germanium alone, which is very close to the theoretical capacity of germanium. The capacity remains almost constant after the fifth cycle. On the other hand, it can be observed that the Ge@C particle electrode shows very fast capacity fading with only a negligible specific capacity value of 185 mA h g⁻¹ at the 100th cycle. The rate capability of the Ge@HCS electrode was evaluated at various current rates, and the obtained results are shown in Figure 3(b) (charging at 0.1 - 20 C and discharging at 0.2 C). The Ge@HCS shows much enhanced rate performance compared to the Ge@C particle sample at all current rates. There was a negligible capacity drop when the charging current was increased from 1 C to 3 C. The discharge capacity was 1153.3 mA h g⁻¹ at the 10th cycle at the rate of 0.1 C, 953 mA h g⁻¹ at the 50th cycle at 5 C, and 878.9 mA h g⁻¹ at the 60th cycle at the rate of 10 C. Even at the high rate of 20 C, the specific capacity remained 772.5 mA h g⁻¹, which is still 67% of its capacity at 0.1 C. Importantly, the specific capacity reached a value of 1140 mA h g⁻¹ after the high rate measurement and therefore almost recovered, implying their good reversibility. In contrast, an extremely low capacity of only 20 mA h g⁻¹ was obtained from the Ge@C particle sample at the rate of 20 C. The fast capacity fading and poor capacity recovery of the Ge@C particles are probably ascribe to the pulverization of germanium particles induced by the unavoidable volume changes during the alloying/de-alloying processes, leading to the loss of electrical contact. Figure 3(c) shows the corresponding galvanostatic voltage profiles of the Ge@HCS composite electrode in the 1st, 2nd, 12nd, 22nd, 32nd, 42nd, 52nd, and 62nd cycles at different rates, showing that all lithium ion insertion and extraction processes are spread over a relatively broad voltage range, and therefore, are also separated temporally.
The much improved cycling stability and rate capability of the Ge@HCS sample may be ascribed to the distinct structure and morphology, which offer the following benefits. Firstly, the hollow carbon spheres can function as a physical matrix to effectively prevent the germanium cores from coalescing into a bulk during lithiation/de-lithiation processes, and also protect the germanium cores against pulverization. Secondly, the germanium cores are interconnected by the shells of the carbon spheres, forming an effective and continuous conductive network to significantly facilitate the diffusion and transport of lithium ions even at high current rates. Thirdly, the inherently porous nature of Ge@HCS with many voids can ensure a high contact area between the electrolyte and electrode materials, and thus facilitate the transport and diffusion of lithium ions. More importantly, the porous property can endow the composite with free space to accommodate the volume changes in the germanium during the lithium ion insertion/extraction processes, thus maintaining the structural integrity of the electrode.

4. Conclusions

In summary, a novel composite consisting of hollow carbon spheres with encapsulated germanium was first synthesized through infiltrating the germanium precursor into the carbon spheres, which were obtained by carbonization of a CTAB modified RF resin coating on silicon template spheres, followed by etching the templates. The cationic surfactant CTAB served as a soft template for mesostructured RF resin formation, resulting in a porous carbon shell, which facilitates the access of the germanium precursor to its hollow center. The obtained Ge@HCS material shows excellent electrochemical properties, which can be attributed to the unique morphology and structure. The voids and vacancies that are formed after the shrinkage of GeO₂ to form germanium can effective accommodate the volume changes during the lithiation/de-lithiation processes, enabling structural integrity and continuity. Meanwhile, the carbon spheres can serve as a network of electronic pathways,
which could increase the kinetics of lithium reactions. The strategy of encapsulating germanium in HCS could offer a new method for developing anode electrodes with high performance.
