Effect of deformation temperature on niobium clustering, precipitation and austenite recrystallisation in a Nb-Ti microalloyed steel

Abstract

The effect of deformation temperature on Nb solute clustering, precipitation and the kinetics of austenite recrystallisation were studied in a steel containing 0.081C–0.021Ti–0.064 Nb (wt%). Thermo-mechanical processing was carried out using a Gleeble 3500 simulator. The austenite microstructure was studied using a combination of optical microscopy, transmission electron microscopy, and atom probe microscopy, enabling a careful characterisation of grain size, as well as Nb-rich clustering and precipitation processes. A correlation between the austenite recrystallisation kinetics and the chemistry, size and number density of Nb-rich solute atom clusters, and NbTi(C,N) precipitates was established via the austenite deformation temperature. Specifically, we have determined thresholds for the onset of recrystallisation: for deformation levels above 75% and temperatures above 825 °C, Nb atom clusters recrystallisation

1. Introduction

Grain refinement is one of the most technologically important strengthening mechanisms in ferritic steels, since a decrease in grain size leads generally to an increase in tensile strength and a decrease in ductile-to-brittle transition (DBTT) temperature [1]. During thermo-mechanical processing (TMP), the final ferrite grain size is largely governed by the prior austenite grain size. The austenite grain size is the result of competition between the driving forces for recrystallisation and grain growth, and grain boundary pinning by solute atoms and precipitates enabled by microalloy additions to the steel. The additions of Nb have been shown to significantly retard the austenite recrystallisation [2, 3]. However, the Nb pinning effect varies depending on whether the Nb atoms are clustered within the austenitic solid solution, or whether these solutes have nucleated as discrete second phase carbo-nitride precipitates; and the specific dispersive properties of these clusters and precipitates will have a key influence. Much research has been undertaken to investigate pinning effect arising from microalloy precipitates such as Nb(C,N) or NbC, much less has been reported on the optimum precipitate dispersion to control recrystallisation, and even less experimental evidence is available on the effects of Nb-rich solute atom clusters on recrystallisation.

Earlier research, carried out on steels microalloyed with 0.01-0.1Nb (wt. %) has shown an increase in the recrystallisation stop temperature, T_{nr} , indicating a retardation of recrystallisation as the Nb content of the steel increases [2]. The Nb(C,N) precipitates were shown to pin grain

boundaries more effectively than the Nb solute atoms [3, 4]. The maximum pinning force was reported for precipitates sized between 1 and 20 nm [5-7]. However, this pinning effect decreases with an increase in temperature, due to the decrease in particle number density following precipitate coarsening, coupled with higher driving forces for boundary migration. The influence of Nb on austenite recrystallisation at high temperature is considered to be predominantly due to solute drag [3, 4, 8], and this effect is considered to be especially significant at low strain levels, short interpass times and high cooling rates [8-11], i.e. in those TMP conditions where recrystallisation is likely to take place prior to precipitation. It has also been found that the Nb precipitation kinetics (time, temperature and particle size) depend strongly on steel composition, in particular the Nb, Ti, C and N contents [2, 12-15], as well as strain levels [16-18]. An increased Nb and N content enhances Nb(C,N) precipitation. The presence of Ti retards Nb(C,N) precipitation, due to a decrease in N and Nb content following precipitation of TiN and TiNb-rich phases. With an increase in strain, the Nb-rich precipitate size decreases, and the number density increases as a result of strain-induced precipitation on dislocations [5, 12, 16]. The strain-induced precipitation retards recrystallisation by delaying recovery. However, when the particles become too fine, they are less effective at grain boundary pinning [2, 10]. Therefore, the Nb pinning effect, and its influence on recrystallisation and grain growth, must be considered in terms of the steel composition and the TMP schedule.

In this paper, we explore the effect of Nb on austenite recrystallisation kinetics in a Nb-Ti-microalloyed steel deformed at three temperatures: above T_{nr} , near T_{nr} , and below T_{nr} . As austenite decomposition takes place on cooling to room temperature in carbon steels, it is not possible to evaluate the atomic distribution in austenite. Thus, all samples were water quenched immediately before or after the deformation in order to minimise the diffusion of substitutional elements. This approach enabled evaluation of the effect of deformation and temperature on the state of Nb before quenching. Characterisation of Nb clustering was performed using atom probe tomography (APT), which has proved to be a highly effective technique for investigation of fine-scale precipitation in steels [19-23]. The precipitation was studied using transmission electron microscopy (TEM). The Nb precipitate/cluster parameters and austenite microstructure have been shown to depend on deformation temperature and prior straining.

2. Material and experimental techniques

The Nb-Ti-microalloyed steel studied here was produced by BlueScope Steel Ltd and possessed composition 0.081C-1.20Mn-0.27Si-0.021Ni-0.019Cr-0.1Mo-0.016Cu-0.037Al-0.064Nb-0.021Ti-0.003V-0.001S-0.012P-0.0047N (wt. %). Samples 10x15x20 mm size were used for TMP simulations after cutting from the quarter thickness position of a 230 mm thick continuously cast slab. The TMP was carried out using a Gleeble 3500 thermo-mechanical simulator. The TMP schedule is summarized in Fig. 1 and involved: reheating for 5 min at 1250 °C; roughing deformation up to 0.35 strain at 5 s⁻¹ strain rate at 1100 °C; cooling at 1 °Cs⁻¹ to each of three deformation temperatures: 1075, 975 and 825 °C, followed by either water quenching to room temperature (to preserve precipitate and cluster population prior to finishing deformation) or finishing deformation up to a strain of 0.75 at a strain rate of 5 s⁻¹ and water quenching to room temperature (to observe influence of deformation on precipitation and cluster development). The water quenching resulted in cooling rate of about 200 °Cs⁻¹, which allows to assume absence of any recrystallisation and precipitation during cooling. As noted earlier, the three finishing deformation temperatures of 1075 °C, 975 °C and 825 °C were selected to be

respectively above, near and below the estimated recrystallization stop temperature (T_{nr}) of ~ 975 °C [24]. Optical microscopy was carried out using a Leica DMRM microscope. The prior austenite grain boundaries were etched in a saturated solution of aqueous picric acid, hydrochloric acid and detergent for 5 min at 68 °C. Austenite grain size was measured using the equivalent circle diameter technique. To obtain the grain size distributions, 800-1000 grains were imaged from the mid-thickness position of each TMP sample.

TEM of Nb-Ti-rich precipitates was carried out using carbon extraction replicas using a JEOL JEM2010 transmission electron microscope operating at 200 kV. For determination of the particle size distributions and the number density values 170 – 240 particle were imaged for each TMP condition. The measurements were manually carried out using TEM micrographs covering the sample area of $39.6 \mu\text{m}^2$ for each TMP condition. Precipitate compositions were determined using energy dispersive X-ray spectroscopy (EDS) point analysis on a Jeol TEM EDS system. For determination of the particle chemistries 20 – 25 particles were analysed for each TMP condition. TEM observations of selected thin foil samples were carried out on a JEOL JEM2200FS field emission gun (FEG) TEM, using an accelerating voltage of 200 kV. The thin foil specimens were prepared by tripod polishing method and ion milling.

Atom probe specimens were prepared by the standard two-stage electropolishing technique [25]. Atom probe data was collected on a Cameca Local Electrode Atom Probe (LEAPTM), operating at a temperature of 20 K and a pulse fraction rate of 20% [26]. The results were carefully analysed and reconstructed using calibrated reconstruction parameters, determined by referring to spatial distribution maps from each individual data set [27]. The matrix composition was determined from the volumes free of visible solute atom segregation using background noise subtraction. The maximum separation envelope method [25, 28] was used to identify carbon segregation to dislocations, clusters and fine precipitates with $d_{\text{max}} = 1$ nm, and $d_{\text{max}} = 2$ nm was used for evaluation of Nb clustering. A minimum of 20 atoms was used to discern Nb-C clusters to minimize the influence of random fluctuations. However, in order to evaluate the solute drag effect of Nb, cluster sizes starting from 2 atoms were analysed. The volumes selected for this analysis were free of visible carbon segregation. The Guinier radii, r_G , of clusters/fine carbides were calculated from radii of gyration (l_g) data using the equation, $r_G = \sqrt{(5/3)} l_g$ [25, 28]. Iso-concentration surfaces were also used for better visualisation of features of interest. Solute segregation to the boundaries was analysed using concentration profiles and Gibbsian Interfacial Excess (GIE) [25, 28].

3. Results

3.1 TMP and optical study of microstructure

As summarized in Fig. 2a, the stress-strain curves recorded during TMP exhibited continuous work hardening when the deformation temperature was 825 °C, and a period of work softening after a strain of about 0.5 when the deformation temperature was 1075 °C. The stress-strain curve for the 975 °C deformation temperature shows an intermediate behavior such that the stress remains constant after a strain of ~ 0.5 . The higher deformation temperature behavior can be attributed to the influence of dynamic recrystallisation (DRX): DRX takes place above the recrystallisation stop temperature, which was ~ 975 °C for this steel [24]. The minimum point on the stress-strain curve second derivative dependence on stress refers to the critical stress value for the start of recrystallisation [29]. It is clear from Fig. 2b that the stress value was not high

enough to initiate recrystallisation during deformation at 825 °C, whereas the DRX was not completed at 975°C.

The quenched microstructures consisted of martensite, which was more refined after the deformation (Fig 3a and d). The prior austenite microstructures for samples quenched before deformation consisted of equiaxed grains (Fig. 3b and c). With a decrease in temperature, the average grain size increased, from $31\pm13\text{ }\mu\text{m}$ for 1075 °C to $51\pm21\text{ }\mu\text{m}$ for 975 °C, due to an increase in cooling time from the roughing temperature of 1100 °C. In the samples quenched after deformation at 1075 °C, a fully recrystallised prior austenite microstructure was observed (Fig. 3e), with the average grain size decreasing to $9\pm4\text{ }\mu\text{m}$. This corresponds to the work softening behavior observed during testing (Fig. 2b) and indicates that DRX occurred under these TMP conditions. In the samples quenched after deformation at 975 °C, a mixture of recrystallised (equiaxed) and non-recrystallised (elongated) grains was observed (Fig. 3f), indicating partial recrystallisation. In the samples quenched after deformation at 825 °C, all the grains were elongated indicating that the microstructure had not recrystallised. This is consistent with the work hardening behavior observed during testing (Fig. 2a).

3.2 TEM study of precipitates

The TEM imaging revealed the presence of 20 – 220 nm precipitates in all the studied samples (Figs. 4 and 5). The EDS data analyses enabled a distinction between various classes of precipitates: (i) coarse ($> 70\text{ nm}$ size) cuboidal Ti-rich and ellipsoidal Nb-rich carbonitrides (Fig. 6a-b); (ii) fine ($< 70\text{ nm}$ size) ellipsoidal Nb-rich carbonitrides and sphere-like Ti-rich carbides (Fig. 6c-d). In some cases, the formation of a Nb-rich cap occurred heterogeneously on the Ti-rich core (Fig. 6e). The particle number density in the $< 70\text{ nm}$ size group and a relative amount of Nb-rich particles both increased after the deformation when compared to the non-deformed condition, and as the deformation temperature decreased (Table 1). This is likely due to an increase in TMP time. No significant variation in the particle parameters was observed in the $> 70\text{ nm}$ size group. No significant variation in the average particle diameter with deformation temperature was observed. However, a slightly higher fraction of $< 70\text{ nm}$ precipitates (Fig. 7) was present in the sample after deformation at 825 °C.

3.3 APT study of atom clusters

The APT data analyses has shown C segregation and Nb solute atom clustering in both non-deformed and deformed austenite, whereas the Nb-C co-clustering was only in deformed austenite. In the samples quenched prior to deformation, the APT data revealed an enrichment of C in what were thought to be martensite lath boundaries and prior austenite grain boundaries (Fig. 8). Element concentration profiles across these two types of interfaces did not show any variation in the substitutional solute element distributions in the regions adjacent to these interfaces (Fig. 8b), suggesting that there was very little substitutional element diffusion on quenching. However, our GIE analysis of what was deduced to be a prior austenite grain boundary revealed a slight enrichment of all alloying elements, in particular Nb (Table 2, Boundary 1). In addition, a C and Ti rich precipitates were observed at the boundaries (Fig. 8c). The arrangement of C atoms in the samples quenched after deformation was similar to that of a lower bainite microstructure: formation of C atmospheres around dislocations and enrichment of C at grain boundaries was present, fine Fe carbides exhibited similar crystallographic orientations (Fig. 9). No detectable difference in the substitutional element concentration in the regions adjacent to either side of the grain boundary was observed, which is similar to the non-

deformed condition. The GIE analysis revealed a depletion of Nb at the grain boundaries in deformed samples (Table 2, Boundary 2), which is in contrast to the measurements from samples in the non-deformed condition. The matrix analysis has shown a variation in Nb solute content in the range of 0.006 - 0.030 at.% for different TMP schedules, compared to 0.038 at.% Nb according to the nominal steel composition. Although some depletion of Nb in solid solution was expected due to the formation of Ti-rich and Nb-rich carbonitrides and carbides, the analysed volume contained very small clusters not apparent by simple inspection of the atom maps: these were detected and analysed using the maximum separation method.

For both non-deformed and deformed conditions, the number density of Nb clusters was observed to decrease as the cluster size increased (Fig. 10). The number density of small clusters (2-3 atoms per cluster) in non-deformed austenite was higher than in deformed austenite for both deformation temperatures of 1075 °C and 975 °C (Fig. 10 a-b). The number density of intermediate sized clusters (4-8 atoms per cluster) was similar for both deformed and non-deformed conditions. However, the maximum cluster size was observed to be larger for the deformed condition compared to the non-deformed (12 vs 8 atoms for 1075°C and 16 vs 11 atoms for 975°C). With a decrease in deformation temperature from 1075 to 975 to 825°C, the maximum cluster size increased respectively from 12 to 16 to 24 atoms. The total Nb cluster number density was measured to be slightly lower in the deformed samples ($3.19 - 3.81 \times 10^7 \mu\text{m}^{-3}$) compared to the non-deformed ones ($4.27 - 4.38 \times 10^7 \mu\text{m}^{-3}$), which may be related to the rearrangement of Nb clusters into Nb-C clusters (see the data below). With a decrease in deformation temperature the cluster number density slightly increased.

The Nb-C co-clusters of 5 - 8 nm (30-55 atoms) size were observed in deformed austenite (Fig. 11 and Table 3). The cluster composition varied with their size. After deformation at 1075 °C and 975 °C the C concentration in the clusters slightly increases with an increase in cluster size, which indicates a possibility of C diffusion to pre-existing Nb clusters. The trend is opposite for the 825 °C sample: with an increase in cluster size the Nb content increased. Some clusters (Fig. 11, e) showed close to 50/50 of Nb/C content ratio, which corresponds to the composition of equilibrium NbC precipitate. However, these Nb-C atom arrangements occurred within the Fe lattice, and no precipitate-like crystallographic orientation of these arrangements was observed. With a decrease in deformation temperature the Nb content in clusters increased, the average cluster size decreased and the number density increased. This corresponds to a decrease in Nb solubility and diffusion rate with a decrease in temperature.

4. Discussion

Austenite grain refinement took place after roughing deformation of 0.35 strain at 1100 °C as a result of recrystallisation. However, a longer time for grain growth was available on cooling to 975 °C finishing temperature, which resulted in a larger grain size compared to that for the sample quenched from 1075°C. As seen from the TEM study, Ti was mostly consumed by coarse Ti nitrides and carbonitrides. The Ti-rich particles were formed upon solidification and remained undissolved during austenitising in Gleeble, due to a short reheating time. Presence of Ti in Nb-rich precipitates raised their solution temperature, compared to that of Ti-free Nb carbonitrides [30]. Therefore, some large TiNb-rich particles were also observed in the quenched samples. Similar findings were reported for a variety of Nb-containing thermo-mechanically processed steels [11, 31-34]. The remaining Ti precipitated as TiC, as found by APT in this work (Fig. 8c). With a decrease in finishing temperature the relative amount of Nb carbonitrides has

increased (Table 1), due to an increase in cooling time (at a constant cooling rate of 1 Cs^{-1}) after roughing. This correlates well with the observed increase in the number density of Nb atom clusters and Nb-rich precipitates in the $< 70\text{ nm}$ size range (Table 6). Before the finishing deformation no interaction between Nb and C atoms was detected, as these elements were forming their own clusters. After the deformation at 1075 and 975°C , the number density of Nb clusters decreased and that of Nb-C clusters increased (Table 4), which can be a result of carbon pipe diffusion along dislocations to pre-existing Nb atom clusters. The Nb cluster, Nb-C cluster and Nb-rich precipitate number densities increased with a decrease in deformation temperature due to an increase in TMP time (time of cooling from the roughing to the finishing deformation temperature). This corresponds to the theoretically predicted and experimentally observed dependences of Nb precipitation kinetics on temperature [16, 17, 35, 36].

The recrystallisation kinetics during hot deformation is influenced by two competing processes: (i) generation of the new dislocations, leading to an increase in the stored energy and formation of subgrain structure and (ii) glide, climb and annihilation of the dislocations (recovery). The recovery of austenite is retarded by both solute Nb atoms and Nb-rich precipitates [37, 38]. Although, the recrystallisation can be retarded by only precipitates of certain size and volume fraction [5-7, 39, 40]. Precipitates could play two roles with respect to recrystallisation: (i) interaction with dislocations during nucleation delaying recovery and (ii) interaction with moving grain boundaries [41, 42]. Using theoretical semi-quantitative model, Hutchinson et al. [7] have shown that NbC precipitates with $1\text{-}5\text{ nm}$ sizes are effective in retardation of recrystallisation for the industrial range of hot rolling temperatures above 900°C , whereas at the temperatures below 900°C the solute drag effect might be more important. As observed in the present work, the number densities of Nb-C clusters and Nb-rich precipitates are low in the samples quenched from both temperatures of 1075°C and 975°C without deformation, which indicates a large amount of Nb remaining in solid solution after roughing. The prior austenite grain structure for these TMP conditions was fully recrystallised and the grain growth took place (Fig. 3b-c). This indicates that in the studied steel Nb in the form of solid solutes and Nb atom clusters (of 11 atom maximum size and $< 4.4 \times 10^7\text{ }\mu\text{m}^{-3}$ number density) was unable to prevent recrystallisation and grain growth.

In the deformed samples the Nb-C clustering / precipitation took place within $1\text{-}2\text{ s}$ during/after the deformation (time before water quench to room temperature), which is slightly quicker than might be expected from the literature data for similar steel chemistries [2, 12, 13, 15-18, 35]. This can be explained by the following. Formation of clusters is preferred at dislocation networks, such as nodes of dislocations, subgrain boundaries, grain boundaries and grain corners. Diffusion of Nb will be faster in these areas due to pipe or boundary diffusion, compared to volume diffusion. Strain level of 0.75 , applied during the second deformation pass, is relatively high, which should lead to the high dislocation density values after the deformation. However, the rate of dislocation annihilation and the mobility of grain boundaries both increase with an increase in temperature. Therefore, the precipitate number density observed after 1075°C deformation was not high enough to pin the grain boundaries effectively and the recrystallisation proceeded. With a decrease in the deformation temperature to 975°C the recovery slowed down. At the same time an increase in the Nb cluster size (up to 16 atoms), formation of $< 8\text{ nm}$ Nb-C clusters and an increase in the number density of the clusters and precipitates took place. As a result of the cluster/precipitate - grain boundary interaction the recrystallisation was retarded during the deformation at 975°C , which led to a partially recrystallised microstructure observed upon quenching.

With a decrease in the deformation temperature to 825 °C the Nb cluster and precipitate number density further increased, which had to result in an increase in the Nb pinning effect. High rate of dislocation structure accumulation, re-arrangement of which was hindered by the presence of fine clusters/precipitates, coupled with the reduced driving force for recrystallisation at low temperature led to the suppression of recrystallisation. It could be suggested that at these conditions, interaction of clusters (< 8 nm size) with dislocation substructure is the main operating mechanism during deformation and immediately after, as it is insufficient time for the strain-induced precipitates to grow. This is in disagreement with the model predictions that solute drag will be a dominant mechanism at temperatures < 900°C [7].

5. Conclusions

A detailed microstructural investigation of TMP Nb-Ti-microalloyed steel has shown the following:

1. At stress-strain-temperature conditions of DRX, the austenite recrystallisation can be rapidly completed within 1-2 s time period. With a decrease in deformation temperature, a higher level of deformation (higher stored energy) would be required to initiate dynamic recrystallisation.
2. Nb precipitation on pre-existing TiN particles, forms (Ti,Nb)(C,N), decreasing the amount of Nb in solid solution and lowering the number density of Nb(C,N) precipitation. In the Ti-microalloyed steels, this reduces the grain boundary pinning effect expected from Nb clustering or precipitation.
3. With a decrease in deformation temperature, the relative amount of Nb-rich precipitates and the number density of Nb-C clusters / precipitates increased, due to a decrease in Nb solubility in austenite and an increase in processing time.
4. Nb solute atom clusters did not suppress austenite recrystallisation and grain growth at a temperature of 1075 °C, which is above T_{nr} for the studied steel.
5. Nb-C solute atom co-clusters < 8 nm size range were shown to be effective to partially or fully suppress austenite recrystallisation at temperatures of 975 °C and 825 °C, which are near and below T_{nr} for the studied steel.

Fig. 1 Schematic diagram of thermo-mechanical processing

Fig. 2 (a) The compression stress-strain curves obtained during the TMP in Gleeble and (b) their second derivative dependences on stress

Fig. 3 Representative martensite microstructures for 1075 °C (a) before and (d) after deformation; and prior austenite microstructures for the samples quenched from (b) 1075 °C and (c) 975 °C, and quenched after deformation at (e) 1075 °C, (f) 975 °C and (g) 825 °C

Fig. 4 Typical TEM micrographs of the Nb-Ti-rich precipitates in austenite for the (a) 1075 °C, (b) 975 °C and (c) 825 °C deformation temperatures (imaging of carbon replica samples)

Fig. 5 Representative (a) STEM bright field image with corresponding EDS maps using (b) Nb and (c) Ti energy peaks for the sample deformed at 825 °C

Fig. 6 Typical TEM micrographs and corresponding EDS spectra of a coarse (a) cuboidal Ti-rich and (b) ellipsoidal Nb-rich; and fine (c) ellipsoidal Nb-rich and (d) spherical Ti-rich particles; (e) a Nb-rich cap precipitation on the Ti-rich core

Fig. 7 The Nb-Ti-rich particle diameter distributions in deformed austenite

Fig. 8 (a) 2 at% C iso-concentration surfaces, atom maps and element concentration profiles (b) across a grain boundary and (c) across a TiC precipitate for the samples quenched prior deformation at 1075 °C

Fig. 9 (a) 2 at% C iso-concentration surfaces, atom maps and element concentration profiles (b) across a grain boundary for the samples quenched after deformation at 1075 °C

Fig. 10 Selected atom maps showing Nb clustering (all other atoms removed for clarity) for the samples deformed at (a) 1075 °C, (b) 975 °C and (c) 825 °C; and the Nb cluster number density variations with cluster size: (d) and (e) show influence of straining at constant temperature, (f) shows influence of the deformation temperature.

Fig. 11 Selected atom maps showing Nb-C cluster arrangements (all other atoms removed for clarity) and the cluster composition variations with cluster size for the samples deformed at (a and d) 1075 °C, (b and e) 975 °C and (c and f) 825 °C.

Table 1 Nb-Ti-rich particle parameters

Temperature, °C	Geometry			Composition		
	size range, nm	number density, μm^{-2}	average diameter, nm	chemistry	shape	%
1075 °C quenched	>70	0.18	94 ± 21	Ti rich + Nb	□	87
				Nb rich + Ti	0	13
	< 70	0.05	60 ± 8	Ti rich + Nb	□	100
				Nb rich + Ti	-	0
975 °C quenched	> 70	0.15	117 ± 30	Ti rich + Nb	□	84
				Nb rich + Ti	0	16
	< 70	0.05	62 ± 7	Ti rich + Nb	□	67
				Nb rich + Ti	0	33
1075 °C deformed	>70	0.12	130 ± 37	Ti rich + Nb	□0	77
				Nb rich + Ti	0	23
	< 70	0.11	51 ± 13	Ti rich + Nb	□0	87
				Nb rich +Ti	0	13
975 °C deformed	>70	0.10	144 ± 41	Ti rich + Nb	□0	80
				Nb rich + Ti	0	20
	< 70	0.14	54 ± 15	Ti rich + Nb	□0	50
				Nb rich +Ti	0	50
825 °C deformed	> 70	0.17	131 ± 36	Ti rich + Nb	□	92
				Nb rich + Ti	0	8
	< 70	0.16	50 ± 13	Ti rich + Nb	□	7
				Nb rich +Ti	0	73

Table 2 Gibbsian interfacial excess ($\times 10^{16} \text{ m}^{-2}$) at the assumed prior austenite grain boundary before deformation (Boundary 1) and after deformation (Boundary 2)

Element	Boundary 1	Boundary 2
Al	-0.7 ± 0.7	85 ± 16
C	254 ± 6.5	3600 ± 65
Fe	-309 ± 35	-4400 ± 430
Nb	1 ± 0.2	-40 ± 2.9
Mo	2.5 ± 0.8	5.2 ± 10
P	-1.5 ± 0.4	43 ± 9.6
Si	7.8 ± 3	670 ± 43
Mn	35 ± 3.8	62 ± 42
V	-0.7 ± 0	-4 ± 2.4
Ni	8.9 ± 1.2	59 ± 26
Cr	5 ± 1	44 ± 9.8
Ti	0.7 ± 0.1	1.7 ± 3.3

Table 3 Characterisation of Nb-C clusters in the deformed austenite

Deformation temperature, °C	Element concentration, at %			Guinier radius, nm	Number of atoms in cluster	Number density, $\times 10^5 \mu\text{m}^{-3}$
	C	Fe	Nb			
1075	70.9 $\pm$ 8.2	6.5 $\pm$ 4.4	22.6 $\pm$ 7.5	2.4	29	1.8
	84.3 $\pm$ 5.6	1.3 $\pm$ 0.9	14.5 $\pm$ 5.4	3.6 $\pm$ 0.5	52 $\pm$ 35	
	91.5 $\pm$ 4.0	5.3 $\pm$ 3.2	3.2 $\pm$ 2.5	3.4 $\pm$ 1.1	57 $\pm$ 35	
975	63.1 $\pm$ 9.0	1.6 $\pm$ 1.6	35.3 $\pm$ 8.9	3.1 $\pm$ 0.5	29 $\pm$ 11	1.9
	84.7 $\pm$ 5.7	5.0 $\pm$ 3.2	10.3 $\pm$ 5.0	2.76 $\pm$ 0.5	36 $\pm$ 17	
825	50.1 $\pm$ 8.7	5.9 $\pm$ 2.8	44.0 $\pm$ 8.6	3.1 $\pm$ 0.1	31 $\pm$ 1	2.1
	65.2 $\pm$ 8.2	3.6 $\pm$ 2.7	31.2 $\pm$ 8.0	3.6 $\pm$ 0.3	33 $\pm$ 8	
	76.2 $\pm$ 6.7	4.8 $\pm$ 3.1	19.0 $\pm$ 6.2	3.4 $\pm$ 0.9	46 $\pm$ 33	

Table 4 Influence of a TMP schedule on the Nb precipitation and austenite recrystallisation

TMP condition	Number density			Austenite condition
	Nb clusters, $\times 10^7 \mu\text{m}^{-3}$	Nb-C clusters, $\times 10^5 \mu\text{m}^{-3}$	Nb-rich particles < 70nm, μm^{-2}	
1075 °C quenched	4.27	no	0	recrystallised + grain growth
975 °C quenched	4.38	no	0.03	recrystallised+ grain growth
1075 °C deformed	3.19	1.8	0.11	DRX
975 °C deformed	3.74	1.9	0.14	partial DRX
825 °C deformed	3.81	2.1	0.16	pancaked, no DRX
