Ambient facile synthesis of gram-scale copper selenide nanostructures from commercial copper and selenium powder

Abstract
Grams of copper selenides (Cu_{2-x}Se) were prepared from commercial copper and selenium powders in the presence of thiol ligands by a one-pot reaction at room temperature. The resultant copper selenides are a mixture of nanoparticles and their assembled nanosheets, and the thickness of nanosheets assembled is strongly dependent on the ratio of thiol ligand to selenium powder. The resultant Cu_{2-x}Se (0 \leq x \leq 0.25) nanostructures were treated with hydrazine solution to remove the surface ligands and then explored as a potential thermoelectric candidate in comparison with commercial copper selenide powders. The research provides a novel ambient approach for preparation of Cu_{2-x}Se nanocrystallines on a large scale for various applications.

ABSTRACT Grams of copper selenides (Cu$_{2-x}$Se) were prepared from commercial copper and selenium powders in the presence of thiol ligands by a one-pot reaction at room temperature. The resultant copper selenides are a mixture of nanoparticles and their assembled nanosheets, and the thickness of nanosheets assembled is strongly dependent on the ratio of thiol ligand to selenium powder. The resultant Cu$_{2-x}$Se (0 ≤ x ≤ 0.25) nanostructures were treated with hydrazine solution to remove the surface ligands and then explored as a potential thermoelectric candidate in comparison with commercial copper selenide powders. The research provides a novel ambient approach for preparation of Cu$_{2-x}$Se nano-crystallines in a large scale for various applications.
Introduction

Transition metal chalcogenides have attracted considerable attention due to the wealth of physical and chemical properties that can be tuned through the careful manipulation of synthesis conditions. Copper selenides are typical transition metal chalcogenides with diverse applications ranging from energy conversion/storage to the biomedical regime,\textsuperscript{1-4} e.g., lithium-ion or sodium-ion batteries,\textsuperscript{5, 6} electrocatalysis,\textsuperscript{7} quantum-dot-sensitized solar cells,\textsuperscript{8, 9} and photothermal therapy.\textsuperscript{10} Some of these applications require large amounts of samples for testing and measuring their performance, e.g., thermoelectric measurement requires gram-scale powders for sintering a small pellet,\textsuperscript{11, 12} photovoltaic test needs tens of individual cells in a batch.\textsuperscript{13-17}

In the thermoelectric regime, introduction of nanoscale structures into conventional thermoelectric bulk materials has been proven to be an effective way for improvement of thermoelectric performance. For example, non-doped $\beta$-phase $\text{Cu}_2\text{Se}$ and $\text{Cu}_{2-x}\text{Se}$ fabricated by high-temperature solid state reaction have a figure of merit, $ZT$, of around 1.5 at 1000 K,\textsuperscript{18} which can be enhanced to 1.7–1.8 at 700$^\circ$C by the introduction of nanoscale precipitates through fast quenching of their liquids in the latest report.\textsuperscript{19} Although various strategies, such as hydrothermal or solvothermal approaches,\textsuperscript{20-30} sonochemistry,\textsuperscript{31, 32} electrochemical-deposition,\textsuperscript{33-35} the microwave-assisted route,\textsuperscript{36} and the cation exchange method,\textsuperscript{37} have been developed to prepare nanoscale copper selenides, most methods are not able to produce large-scale samples for thermoelectric, photovoltaic, or other applications. For example, the yield of copper selenide nanomaterials prepared from hydrothermal or solvothermal approaches are limited by the volume, temperature, and pressure of Teflon-lined autoclaves, which make difficulties for scale-up preparation. Jiang et al prepared $\text{Cu}_{2-x}\text{Se}$ nanostructures from CuO and Se powder in a mixture of ethylenediamine and hydrazine hydrate at room temperature. The use of expensive
and corrosive mixed solvents leads to a high cost.\textsuperscript{38} Sonochemistry, electrochemical-deposition, and the microwave-assisted routes are energy-consuming and also face the difficulties in large-scale preparation. For the ion exchange method, the replacement reactions between cations or anions are strongly relied on the size, morphology, and amount of nano-scaled precursors, and it couldn’t be adopted for large-scale preparation. An alternative approach is the high-energy ball-milling method,\textsuperscript{12} which is energy-consuming and time-consuming. Thus, a facile synthesis of copper selenide on a large scale is desirable.

In this work, large amounts of Cu$_{2-x}$Se nanostructures were synthesized through the ambient reaction of commercial copper powders with selenium powders in the presence of 2-mercaptopethanol and traces of NaOH. The as-prepared samples were treated with hydrazine solution to remove the adsorbed surface ligands. The resultant Cu$_{2-x}$Se nanoparticles were sintered into pellets for investigation of their thermoelectric properties in comparison with commercial Cu$_2$Se powder, which was sintered and measured under the same conditions. The obtained $ZT$ is comparable to that of the commercial samples and reaches 0.28 at 480°C.

**Experimental section**

**Chemical Reagents.** Copper powder (-150 mesh, 99.5%), 2-mercaptopethanol (> 99.0%), hydrazine solution (35 wt% in H$_2$O), and anhydrous ethanol (> 99.5%) were purchased from Sigma-Aldrich and used as received. Sodium hydroxide (97.0%) and selenium powder (-325 mesh, 99.5%) were bought from Alfa Aesar.

**Synthesis of Cu$_{2-x}$Se nanostructures.** Cu powder (0.06 mol), 12.6 mL 2-mercaptopethanol (0.18 mol), 1 mL NaOH (7 M), and 100 mL anhydrous ethanol were loaded into a 250 mL glass flask. The mixture was stirred for 5 min, and Se powder (0.03 mol) was added into the mixture.
The color of the mixture gradually turned to black, suggesting the reaction of reddish copper with gray selenium powder. After the mixture was reacted for 24 h under gentle stirring, black precipitates were separated by centrifuge. These precipitates were dispersed in 20 mL hydrazine solution and stirred overnight. The precipitates were separated, washed with distilled water and ethanol several times, and then dried in vacuum at room temperature.

**Characterization.** X-ray diffraction (XRD) patterns for all samples were collected using Cu Kα radiation (λ = 1.5406 Å) at 40 kV and 25 mA at a scanning rate of 2° min⁻¹ for 2θ in the range of 20-80°. Energy dispersive X-ray spectroscopy (EDS), X-ray photoelectron spectroscopy (XPS), inductively coupled plasma – atomic emission spectroscopy (ICP-AES), and Raman spectroscopy with a 10 mW He/Ne laser at 632.8 nm (Jobin Yvon HR800) were used to characterize the chemical composition and crystal structure of the samples. The weight loss of the samples was measured with a Mettler-Toledo thermogravimetric analysis/differential scanning calorimetry (TGA/DSC) instrument from 50-900 °C, with a heating rate of 5 °C min⁻¹ in argon. Field emission scanning electron microscope (FE-SEM) images of all the samples were collected using a JEOL JMS 7500-FA microscope with an accelerating voltage of 5 kV and a secondary electron detector. The transmission electron microscope (TEM) images were collected on a JEOL ARM-200F microscope and a JEOL 2011 microscope operated at 200 kV.

**Thermoelectric measurements.** The hydrazine-treated copper selenide nanopowders were loaded into a graphite die with a diameter of 20 mm and sintered into a pellet at 430 °C under 65 MPa for 10 min by the spark plasma sintering (SPS) technique. The resultant pellet was cut into pieces and polished into parallelepipeds with dimensions of ~2 mm × 3 mm × 10 mm. The parallelepipeds were coated with a layer of boron nitride to protect the instrument against evaporation of the elements. The electrical conductivity and the Seebeck coefficient were
measured simultaneously under helium atmosphere from room temperature to 480 °C using an Ozawa RZ2001i (Japan). A Linseis LFA1000 (Germany) instrument was used to determine the thermal diffusivity of samples that were cut and polished into a disk shape with a diameter of 10 mm and a thickness of 1 mm. The thermal conductivity (κ) was calculated using Equation (1):

\[ \kappa = D \times C_p \times \rho \] (1)

where \( D \) is the thermal diffusivity, \( C_p \) is the heat capacity, and \( \rho \) is the density of the sample, which was calculated using the geometrical dimensions of the specimen and its mass. The heat capacity was determined using the differential scanning calorimetry (DSC) method.

**Results and discussion**

Copper selenide was fabricated from commercial copper powders and selenium powders in the presence of 2-mercaptoethanol at room temperature, and the resultant nanostructures were treated with hydrazine solution to remove surface organic material, which can influence the thermoelectric properties of pellets sintered from nanopowders due to the evaporation of organics during sintering and measurement at high temperature. Figure 1 shows FESEM and TEM images of the non-treated sample. A mixture of nanoparticles and their assembled nanosheets were observed [Figure 1(a-c)], in which the nanosheets have a thickness of around 7 nm (Figure S1 in Supporting Information). The selected-area electron diffraction (SAED) pattern in the inset of Figure 1(c) also indicates the polycrystalline nature of the products, which is consistent with the random orientation of the crystal lattice, as shown by the high-resolution TEM (HRTEM) image of the selected area [Figure 1(d)]. The sheet structure was destroyed after treatment with hydrazine solution due to the removal of ligands (Figure S2), which indicates that nanoparticles were assembled with the assistance of ligands. The HRTEM images of both non-
treated and treated samples clearly display lattice fringes with a spacing of 0.33 nm, matching well with the (111) planes of cubic Cu$_{2-x}$Se [Figure 1(d), S2(c)]. These results suggest that removal of surface organic ligands by hydrazine did not influence the crystal structure. To confirm their crystal structures, XRD patterns of treated and non-treated samples were collected [Figure 2(a)]. All the peaks of both samples match well with standard peaks of face-centred-cubic (fcc) Cu$_2$Se (JCPDS 88-2043), demonstrating that no crystal structure or phase change occurred after treatment with hydrazine, although the morphology was drastically modified after treatment. The strong and sharp diffraction peaks suggest that both samples are well-crystallized, despite our room-temperature synthesis and modification. The average Cu/Se ratios in non-treated and treated samples were determined to be 1.91 and 1.95 by ICP-AES.

To demonstrate the successful removal of surface organic material, TGA was used to compare the weight loss of samples before and after hydrazine treatment [Figure 2(b)]. The weight loss was reduced from 13% to only 3% after hydrazine treatment, which means that most of the surface ligands were removed. Raman spectroscopy was further applied to demonstrate the removal of surface ligands. The spectra of both the non-treated and the treated Cu$_{2-x}$Se samples clearly show the characteristic vibration of the Cu-Se bond at 256 cm$^{-1}$ (Figure S3).$^{40-42}$ The spectra also confirm the absence of the typical peak of the –SH group at 2500-2600 cm$^{-1}$. It is well known that Cu$_{2-x}$Se is easy to oxidize,$^{2, 44}$ and XPS was used to determine the ratio of different valence states of Cu (i.e., Cu$^+/Cu^{2+}$) in both non-treated and treated Cu$_{2-x}$Se samples (Figure 3). The XPS spectra of Cu 2p confirm the presence of both Cu$^+$ and Cu$^{2+}$ in both samples [Figure 3(a, c)]. The ratio of Cu$^+/Cu^{2+}$ increases from 6.8 to 8.3 after the treatment with hydrazine due to the reduction capability of hydrazine.$^{45-47}$ The spectra of Se 3d in both samples suggest the existence of Se$^{2-}$ at 53.8 eV [Figure 3(b, d)]. A small peak at 58.2 eV in the original
sample is attributed to the adsorbed organic selenide on its surface [Figure 3(b)],\(^2,48\) which was successfully removed after treatment [Figure 3(d)].

Previous reports on the preparation of high crystalline metal chalcogenides, such as CuSe made from copper and selenium in pure 2-mercaptoethanol,\(^49\) and Bi\(_2\)S\(_3\) nanorods prepared from bismuth(III) monosalicylate in the presence of thioglycolic acid, demonstrates that the key role of -SH group is to provide S\(^2-\) or dissolve selenium to form highly reactive selenothiolate.\(^50-53\) Theoretical calculations show that the reaction between copper and reactive selenothiolate (e.g., HOCH\(_2\)CH\(_2\)SSe\(^-\)) is spontaneous.\(^54\) The influence of 2-mercaptoethanol on the Cu\(_{2-x}\)Se nanostructures was investigated (Figure 4). The ratio between Cu and 2-mercaptoethanol was varied from 1/3, through 1/5, 1/7, 1/10, 1/20, and 1/30, to 1/50. The resultant nanostructures are nanosheets assembled from nanoparticles and their thickness increases with increasing concentration of 2-mercaptoethanol (Figure 4). The average thickness of the nanosheets obtained from the ratio of 1/3 is 7 nm (Figure S1), and it increases through 11 nm, 15 nm, 18 nm, 23 nm, and 29 nm, to 47 nm with the ratio of Cu/2-mercaptoethanol increasing from 1/3, through 1/5, 1/7, 1/10, 1/20, and 1/30, to 1/50, respectively. These results demonstrate that more 2-mercaptoethanol promotes the growth of nanoparticles along the [111] direction, which is the automatically smooth surface with the lowest energy in the fcc structure.\(^55\) The XRD patterns of all the products (Figure S4) are matched well with fcc Cu\(_2\)Se (JCPDS 88-2043), which means that the use of more 2-mercaptoethanol did not influence the crystal structure of Cu\(_{2-x}\)Se.

The evolution of the nanostructures was investigated in the case of the Cu/2-mercaptoethanol ratio of 1/50. The original commercial Cu powder is irregular and rough [Figure S5(a)]. 5 min after the addition of selenium powder into the reaction solution, small nanoparticles were formed and assembled into thin nanosheets with assistance of thiol ligands [Figure S5(b)]. Increasing the
reaction time led to the growth of small nanoparticles and the assembling of nanoparticles [Figure S5(c-f)]. The XRD patterns of all the samples also confirm the evolution of the nanostructures and the transformation of Cu into Cu$_{2-x}$Se (Figure S6). The product obtained within a short reaction time (i.e., 5 min) is a mixture of Cu and Cu$_{2-x}$Se, as indicated by the high intensity of the Cu peaks and the very weak peaks from Cu$_{2-x}$Se in its XRD pattern. Extended reaction time led to more Cu$_{2-x}$Se being formed and an increase in the intensity of the Cu$_{2-x}$Se peaks in the corresponding XRD patterns. The pure Cu$_{2-x}$Se obtained after 24 h reaction demonstrates the complete transformation of Cu into Cu$_{2-x}$Se.

An advantage of our method is that it is capable of producing grams of Cu$_{2-x}$Se nanostructures in a one pot reaction for investigation of their properties and applications. As mentioned previously, copper selenides such as Cu$_{2-x}$Se and Cu$_2$Se could be candidate of thermoelectric materials. We investigate the thermoelectric properties of the as-synthesized Cu$_{2-x}$Se nanostructures in comparison with commercial Cu$_2$Se powder. Both synthetic and commercial powders were sintered by SPS, and the resultant pellets were cut into pieces of a similar size and then measured under the same conditions. As shown in Figure 5(a), the electrical conductivity of the synthetic Cu$_{2-x}$Se sample is higher than that of the commercial Cu$_2$Se powder from room temperature to 480 °C. Due to its excellent electrical conductivity, the Seebeck coefficient of Cu$_{2-x}$Se is lower than that of the commercial sample (i.e., 35 μV/K at room temperature and 80 μV/K at 480 °C) [Figure 5(b)]. Following the same trend as with the Seebeck coefficient, this sample has a power factor (PF) of 0.3 μW·cm$^{-1}$K$^{-2}$ at room temperature and 3.5 μW·cm$^{-1}$K$^{-2}$ at 480 °C, lower than the corresponding values for the commercial sample [Figure 5(c)]. Heat capacities ($C_p$) were measured and are shown in Figure 5(d). A sharp endothermal peak at around 140°C was observed in both the Cu$_{2-x}$Se and the commercial samples. The overall thermal
conductivity of the Cu$_{2-x}$Se and commercial samples calculated from Equation (1) demonstrates that our Cu$_{2-x}$Se sample has lower thermal conductivity than that of the commercial Cu$_2$Se sample [Figure 5(e)]. The figures of merit for our Cu$_{2-x}$Se and the commercial sample were calculated from Equation (2).

\[
ZT = \frac{S^2 \sigma T}{\kappa}
\]

(2)

where \( S \), \( \sigma \), \( \kappa \), and \( T \) are the Seebeck coefficient, the electrical conductivity, the thermal conductivity, and the absolute temperature, respectively. The calculated \( ZT \) values of the Cu$_{2-x}$Se and Cu$_2$Se samples are plotted in Figure 5(f), where a slight decrease in \( ZT \) at 140°C can be observed due to the presence of a sharp endothermal peak at this temperature [Figure 5(d)]. The \( ZT \) values of our Cu$_{2-x}$Se and the commercial sample increase with increasing temperature, and reach 0.28 and 0.38 at 480°C, respectively. These results are also similar to that for Cu$_{2-x}$Se prepared from a high-temperature solid state reaction.\(^57\)

The higher electrical conductivity and lower overall thermal conductivity of our Cu$_{2-x}$Se sample could be attributed to its stable crystal structure, which was re-examined after SPS sintering and thermoelectric measurements. The XRD patterns show that there was no phase transition in the Cu$_{2-x}$Se sample after sintering and measurement at high temperature, except that the peaks became narrower and sharper due to the improvement in crystallization at high temperature [Figure 6(a)]. The original as-received commercial Cu$_2$Se powder consists of cubic and orthorhombic phases, however, the fraction of orthorhombic Cu$_2$Se became pronounced after it was sintered into a pellet under the same conditions, and it was completely transformed into the orthorhombic structure after high-temperature measurements [Figure 6(b)]. The disordered Cu ions in the cubic structure at high temperature would be highly efficient phonon scattering
centres as compared with the orthorhombic structure, which increase the carrier concentration. The average Cu/Se ratios in pellets of our Cu$_{2-x}$Se and the commercial samples after SPS and measurement were determined to be 1.93 and 2.02, respectively, by ICP-AES, which shows a higher Cu deficiency in the Cu$_{2-x}$Se sample. Increased carrier concentration enhances the electrical conductivity according to Equations (3-4), however, the Seebeck coefficient of the Cu$_{2-x}$Se compounds was found to decrease with increasing carrier concentration.

$$\rho = \frac{1}{\mu ne} \quad (3)$$

$$\alpha = \frac{k}{e}(r - \ln \frac{n}{N_0}) \quad (4)$$

where $\rho$, $\mu$, $n$, $e$, $\alpha$, $k$, $r$, and $N_0$ are the electrical resistivity, carrier mobility, carrier concentration, charge of the electron, Seebeck coefficient, Boltzmann’s constant, scattering factor, and Avogadro constant, respectively. In addition to the liquid-like behaviour of copper ions at high temperature, the lower thermal conductivity of our Cu$_{2-x}$Se sample could be also due to the presence of nanoscale grains, pores, and boundaries in the pellet, which can effectively improve the phonon scattering and decrease the thermal conductivity. SEM images of pellets made from Cu$_{2-x}$Se nanoparticles and commercial Cu$_2$Se powder in Figure 6(c-d) clearly show that the Cu$_{2-x}$Se pellet has a larger amount of nanoscale particles and pores than the Cu$_2$Se pellet, although they were sintered under the same conditions (i.e., 430°C, 65 MPa, and 10 min) by SPS technology. In addition, the pronounced Cu-deficiency in the Cu$_{2-x}$Se sample leads to more vacancies, which are also responsible for its lower thermal conductivity.

Conclusions
Grams of Cu$_{2-x}$Se nanostructures have been synthesized by a one-pot reaction of commercial copper powder with Se powder in the presence of 2-mercaptoethanol. The resultant nanostructures were treated with hydrazine solution to remove adsorbed surface ligands. The hydrazine treatment destroyed the sheet-like structure, and resulted in pristine Cu$_{2-x}$Se nanoparticles, which were sintered into a pellet. Their thermoelectric properties were measured in comparison with commercial Cu$_2$Se powder under the same conditions. Their thermoelectric properties show that the Cu$_{2-x}$Se sample has a similar temperature-dependent $ZT$ ($0.28$ at $480^\circ$C) to that of the commercial sample. The Cu$_{2-x}$Se sample retained the same crystal structure and morphology after SPS sintering and thermoelectric measurements at high temperature. Our research provides a simple way to prepare large-scale copper selenide nanostructures for diverse applications.
