Electrocatalytically inactive SnS₂ promotes water adsorption/dissociation on molybdenum dichalcogenides for accelerated alkaline hydrogen evolution

Abstract

Molybdenum dichalcogenides, in particular, MoS₂ and MoSe₂, are very promising nonprecious metal-based electrocatalysts for hydrogen evolution reaction (HER) in acidic media. They exhibit inferior alkaline HER activity, however, due to the sluggish water dissociation process. Here, we design and synthesize new molybdenum dichalcogenide-based heterostructures with the basal planes decorated with SnS₂ quantum dots towards enhanced alkaline HER activity. The electrochemical results reveal that the alkaline hydrogen evolution kinetics of molybdenum dichalcogenides is substantially accelerated after incorporation of SnS₂ quantum dots. The optimal MoSe₂/SnS₂ heterostructure delivers a much lower overpotential of 285 mV than MoSe₂ (367 mV) to reach a current density of 10 mA cm⁻² in 1 M KOH. The improved catalytic activity is predominantly owing to the enhanced water dissociation kinetics of the heterostructures with well-defined interfaces. Density functional theory (DFT) calculations reveal that the presence of SnS₂ significantly promotes the water adsorption capability of MoSe₂ nanosheets, which consequently facilitates the subsequent water dissociation process. These results open up a new avenue for the rational design of well-defined heterostructures with enhanced water adsorption/dissociation capability for the development of high-performance alkaline HER electrocatalysts.

1. Introduction

Our severe energy and environmental crisis makes it imperative to search for clean and sustainable energy sources as alternatives to traditional fossil fuels.^[1-3] Owing to its having the highest gravimetric energy density and carbon-free emissions, hydrogen produced by renewable energy sources is considered to be the most promising energy carrier for our future society's energy.^[4-5] Currently, hydrogen is mostly produced from fossil fuels by steam reforming.^[6] Alternatively, photocatalytic, photoelectrocatalytic, or electrocatalytic water splitting driven by renewable energy would make hydrogen a real carrier for clean energy.^[7-9] With regards to electrocatalytic water splitting, electrocatalytic performance remains unsatisfactory for both the cathodic hydrogen evolution reaction (HER) and the anodic oxygen evolution reaction (OER), although numerous research efforts have been devoted to developing efficient electrocatalysts. Currently, precious metal-based materials are the state-of-the-art catalysts for both the HER (e.g., Pt) and the OER (e.g., IrO₂), but they suffer from high cost and scarcity.^[10-17] Therefore, developing earth-abundant and low-cost alternatives, such as transition metal chalcogenides, metal oxides/hydroxides, and metal alloys, is critically necessary to address this challenge for practical water splitting systems.^[18-21]

Molybdenum dichalcogenides, in particular MoS₂ and MoSe₂, are very promising nonprecious-metal-based electrocatalysts for the HER.^[22-24] Both density functional theory (DFT) calculations and experimental findings have demonstrated that the HER catalytic activity of molybdenum dichalcogenides is mainly derived from their edge sites.^[25-29] In this regards, various strategies have been focused on increasing the number of exposed active sites of

molybdenum-dichalcogenide-based electrocatalysts through building various nanostructures, engineering surface defects, or heteroatom doping.^[30-32] Unfortunately, although the molybdenum dichalcogenide-based electrocatalysts thus developed display impressive catalytic activity in acidic media, they exhibit inferior HER activity in alkaline media due to the sluggish water dissociation kinetics. Basically, alkaline HER involves water adsorption, water dissociation, and hydrogen recombination and release.^[33] Water adsorption and dissociation take place at the beginning of the alkaline HER process and are considered to represent the rate-determining step for the alkaline HER.^[34-37] Therefore, designing electrocatalysts with enhanced water adsorption and dissociation capability is the key for the promotion of alkaline HER catalytic activity. Recently, molybdenum-dichalcogenide-based heterostructures with an additional phase (e.g., Ni(OH)₂) anchored on MoS₂ or MoSe₂ nanosheets were reported as efficient alkaline HER catalysts.^[38-40] The second phases usually possess strong water affinity and water adsorption capability, which are of great significance for accelerating the water dissociation kinetics of the heterostructured catalysts.^[41] Meanwhile, in some cases, the presence of the second phase can also modulate the electronic structure of Mo and optimize the hydrogen adsorption energy.^[42-44] On the other hand, heteroatom doping (e.g., Ni, Co) was also demonstrated to be an effective strategy for enhancing alkaline HER kinetics.^[45-46]

In this work, we propose a new heterostructured design concept in order to improve the alkaline HER activity of molybdenum dichalcogenides. MoSe₂/SnS₂ and MoS₂/SnS₂ heterostructures with SnS₂ quantum dots decorated on the basal planes are synthesized by a universal wet-chemical strategy for enhanced alkaline HER. DFT calculations reveal that the incorporation of SnS₂ brings in the substantial enhancement of water adsorption capability of MoSe₂ both on the edge sites and basal planes. Benefiting from the improved water adsorption/dissociation

capability, the well-defined heterostructures delivered significantly enhanced hydrogen evolution kinetics in alkaline media.

2. Experiment section

2.1 Materials synthesis

Synthesis of MoSe₂ nanosheets. MoSe₂ nanosheets were synthesized by a modified hydrothermal process.^[32] Briefly, 241.95 mg Na₂MoO₄·2H₂O was added to 20 ml deionized water (DI water) under magnetic stirring as the Mo precursor. Then, 0.1 g NaBH₄ was dissolved in 15 ml Ar saturated DI water in a three-neck bottle. Subsequently, 0.16 g Se powders were dispersed into the NaBH₄ aqueous solution under Ar flow with mild shaking until Se powders were fully dissolved to form a homogeneous transparent NaHSe solution, which was used as the Se source. Next, the Mo and Se source solutions were transferred into a 50 ml Teflon-lined stainless steel autoclave, purged with Ar for 30 min, and then heated in an oven at 180 °C for 24 h. After cooling down to room temperature, the as-prepared product was collected by centrifugation, washed with DI water and ethanol for several times, and dried at 60 °C under vacuum overnight.

Synthesis of MoSe₂/SnS₂ heterostructures. For the preparation of MoSe₂/SnS_{2-2.5}, 7.12 mg SnCl₄·5H₂O and 6 mg thioacetamide (TAA) were added together into the as-obtained MoSe₂ dispersion solution (0.36 mg ml⁻¹ in the mixture of 15 ml DI water and 20 ml ethylene glycol). After 1 h sonication, the mixed solution was transferred into a 50 ml Teflon-lined stainless steel autoclave and heated in an electric oven at 180 °C for 24 h. After cooling down to room temperature, the obtained MoSe₂/SnS_{2-2.5} was collected by centrifugation at 8000 rpm for 5 min, then repeatedly washed with DI water and ethanol, and finally dried at 60 °C under vacuum overnight. MoSe₂/SnS_{2-x} ($x = 1.5, 5.0, 10$) was prepared following the same procedure as for MoSe₂/SnS_{2-2.5} with different molar ratios of Mo and Sn precursors (Mo/Sn = 1.5, 5.0,

and 10). The Mo/Sn atomic ratios in the MoSe₂/SnS₂ heterostructures (MoSe₂/SnS₂-1.5: Mo/Sn = 3.5; MoSe₂/SnS₂-2.5: Mo/Sn = 4.7; MoSe₂/SnS₂-5.0: Mo/Sn = 7.0; MoSe₂/SnS₂-10: Mo/Sn = 12.6) were determined using inductively coupled plasma – optical emission spectrometry (ICP-OES, Perkin-Elmer, Optima 7300DV) with mass spectrometry.

Synthesis of MoS₂/SnS₂ heterostructures. For the preparation of pure MoS₂, 72.6 mg Na₂MoO₄·2H₂O and 45.7 mg thiourea were firstly added into DI water (35 ml) under sonication for 10 mins. Then, the homogeneous solution was transferred into a 50 mL autoclave for hydrothermal reaction at 180 °C for 24 h. After cooling down to room temperature, the as-prepared MoS₂ was collected by centrifugation, washed with DI water and ethanol several times, and dried at 60 °C under vacuum overnight. For the preparation of MoS₂/SnS₂-2.5, 7.12 mg SnCl₄·5H₂O and 6 mg TAA were added together into the as-obtained MoS₂ dispersion solution (0.232 mg ml⁻¹ in the mixture of 15 ml DI water and 20 ml ethylene glycol). After 1 h sonication, the mixed solution was transferred into the 50 ml Teflon-lined stainless steel autoclave and heated in an electric oven at 180 °C for 24 h. Finally, the MoS₂/SnS₂-2.5 product was collected after centrifugation, washing, and drying. MoS₂/SnS₂-*x* (*x* = 1.5 and 5.0) was prepared following the same procedure as for MoS₂/SnS₂-2.5 with different molar ratios of Mo and Sn precursors (Mo/Sn = 1.5 and 5.0)

2.2 Physical Characterization

X-ray diffraction (XRD) was carried out using a GBC MMA X-ray diffractometer ($\lambda = 1.5406$ Å, 25mA, 40 Kv, step size of 0.02° s⁻¹). The morphology and microstructures of the samples were characterized by transmission electron microscopy (TEM, JEM-2010, working voltage 200 kV). The scanning transmission electron microscopy (STEM) elemental mappings were conducted on the JEOL ARM-200F at 200 kV equipped with an EDS detector. X-ray photoelectron spectroscopy (XPS) measurements were performed on a Thermo ESCALAB

250Xi instrument with monochrome Al K α ($h\nu = 1486.6$ eV) as the X-ray excitation source. The Mo/Sn atomic ratios in the MoSe₂/SnS₂ heterostructures were obtained by ICP-OES.

2.3 Electrochemical measurements

All the electrochemical measurements were performed with a typical three-electrode electrochemical cell equipped with the rotating disk electrode (Pine Research Instruments, Inc.) and electrochemical workstation (Multichannel potentiostat/galvanostat VSP-300, BioLogic Science Instrument). Hg/HgO (1 M KOH solution) and Ag/AgCl (saturated KCl solution) were used as the reference electrode in 1 M KOH and 0.5 M H₂SO₄ aqueous solution, respectively. The platinum wire was employed as the counter electrode, and the glassy carbon electrode (0.196 cm²) coated with different catalyst inks was used as the working electrode. The catalyst inks were prepared as follows. 2 mg catalyst was dispersed into a mixed solvent composed of 16 μ L Nafion solution (Aldrich Co., 5 wt%), 384 μ L deionized water, and 100 μ L isopropanol under sonication for 30 min. 10 μ L of catalyst ink (containing 40 μ g of catalyst) was coated onto the polished glassy carbon electrode and dried at room temperature. The electrolyte was continuously purged with N₂ to remove O₂ during the measurements. The working electrode was constantly rotated at 1600 rpm to remove the generated H₂ and eliminate concentration polarization of electrolyte ions during electrochemical testing. Linear sweep voltammetry (LSV) polarization curves were collected at a scan rate of 5 mV s⁻¹. All LSV curves were corrected with 95% *iR*-compensation. Electrochemical impedance spectra (EIS) were collected at -0.1 V (vs. RHE) in the frequency range of 1.0 –100 kHz.

The electrochemical active surface area (ECSA) was evaluated by calculating the double-layer capacitance (C_{dl}) in 1 M KOH.^[47] The cyclic voltammetry (CV) curves were performed at scan rates from 40 to 140 mV s⁻¹ in the range of -100 – 0 mV vs. RHE. The C_{dl} values were calculated according to the equation:

$$j = vC_{dl} \quad (1)$$

Where the capacitive current j (A) can be obtained by $\frac{J_a - J_c}{2}$. J_a and J_c represent anodic current and cathodic current at -50 mV vs. RHE, respectively, v (mV s^{-1}) is the scan rate.

The turnover frequency (TOF) was calculated according to the following equation:

$$TOF = \frac{\text{Total number of H}_2 \text{ molecules per second}}{\text{Total number of active sites per unit area}} = \frac{j}{2 \times q \times N} \quad (2)$$

Where $q = 1.6 \times 10^{-19}$ C stands for the elementary charge, j represents current (A) from the linear sweep measurement, N stands for the number of total Mo atoms, and 2 represents that two electrons are required to generate one H_2 molecule.

3. Results and discussion

Scheme 1. Illustration of the synthesis of $\text{MoSe}_2/\text{SnS}_2$ heterostructures.

The molybdenum dichalcogenide heterostructures were prepared via a two-step hydrothermal method, as illustrated in Scheme 1. The molybdenum dichalcogenide nanosheets were first prepared, and then SnS_2 quantum dots were uniformly anchored on the nanosheet surfaces via an in situ precipitation process (See Experimental Section for more details). The X-ray diffraction (XRD) pattern of $\text{MoSe}_2/\text{SnS}_2$ (Figure S1, Supporting Information) presents typical diffraction peaks that can be well indexed to SnS_2 (JCPDS No. 23-0667) and MoSe_2 (JCPDS No. 29-0914). Figure 1a shows the transmission electron microscopy (TEM) analysis, SnS_2 quantum dots with a size of 3-5 nm were uniformly grown on the surfaces of MoSe_2 nanosheets,

which could reduce agglomeration. Also, the typical lattice spacings of 0.32 and 0.26 nm could be indexed to the (100) planes of SnS₂ and the (102) planes of MoSe₂, respectively. In Figure 1b, the high-resolution transmission electron microscopy (HRTEM) image provides more detailed structural information. It can be shown that the markedly striped patterns are in good agreement with the MoSe₂ edge surface of (002) planes, while the SnS₂ quantum dots were aligned along the [001] *c*-axis in intimately contact with the MoSe₂ surface. The corresponding Fast Fourier transform (FFT) pattern (Figure 1c) clearly indicates the co-existence of (102) and (002) planes of MoSe₂, and (100) and (101) planes of SnS₂, further revealing the formation of MoSe₂/SnS₂ heterostructures. The scanning transmission electron microscopy (STEM) elemental mapping results further reveal the spatial distribution of Mo, Se, Sn, and S in the MoSe₂/SnS₂ heterostructures (Figure 1d). Moreover, the MoSe₂/SnS₂ heterostructures with different Mo/Sn atomic ratios could be precisely controlled by varying the ratio of the precursors (Figure S2, Supporting Information).

The X-ray photoelectron spectroscopy (XPS) survey spectrum of the MoSe₂/SnS₂ heterostructures confirmed the coexistence of Mo, Se, Sn, and S elements (Figure S3, Supporting Information). After deposition of the SnS₂, the binding energies of Mo 3d and Se 3d are shifted negatively by 0.2 and 0.3 eV, respectively (Figure 1e-f). Along with the negative shift in the binding energy, the surface negative charge density of MoSe₂ will be increased. As a result, the H atoms of water molecules are more accessible to the negative charges, so that an attractive interaction between water molecules and the surface of MoSe₂ is enhanced accordingly.^[26, 48] In other words, the negative shift in the binding energy for Mo and Se effectively promotes the adsorption capability of water molecules. Also, the negative shift in the binding energy for MoSe₂ demonstrates the transfer of electrons from SnS₂ to MoSe₂, which helps to improve the conductivity of MoSe₂.^[43-44] Moreover, a positive shift of 0.5 eV can be observed for the binding energy of Sn 3d in MoSe₂/SnS₂ as compared to SnS₂ (Figure 1g).

These results demonstrate that the charge redistribution across the interfaces of MoSe₂/SnS₂ heterostructures is beneficial to increase the water adsorption capability and improve the conductivity of MoSe₂.

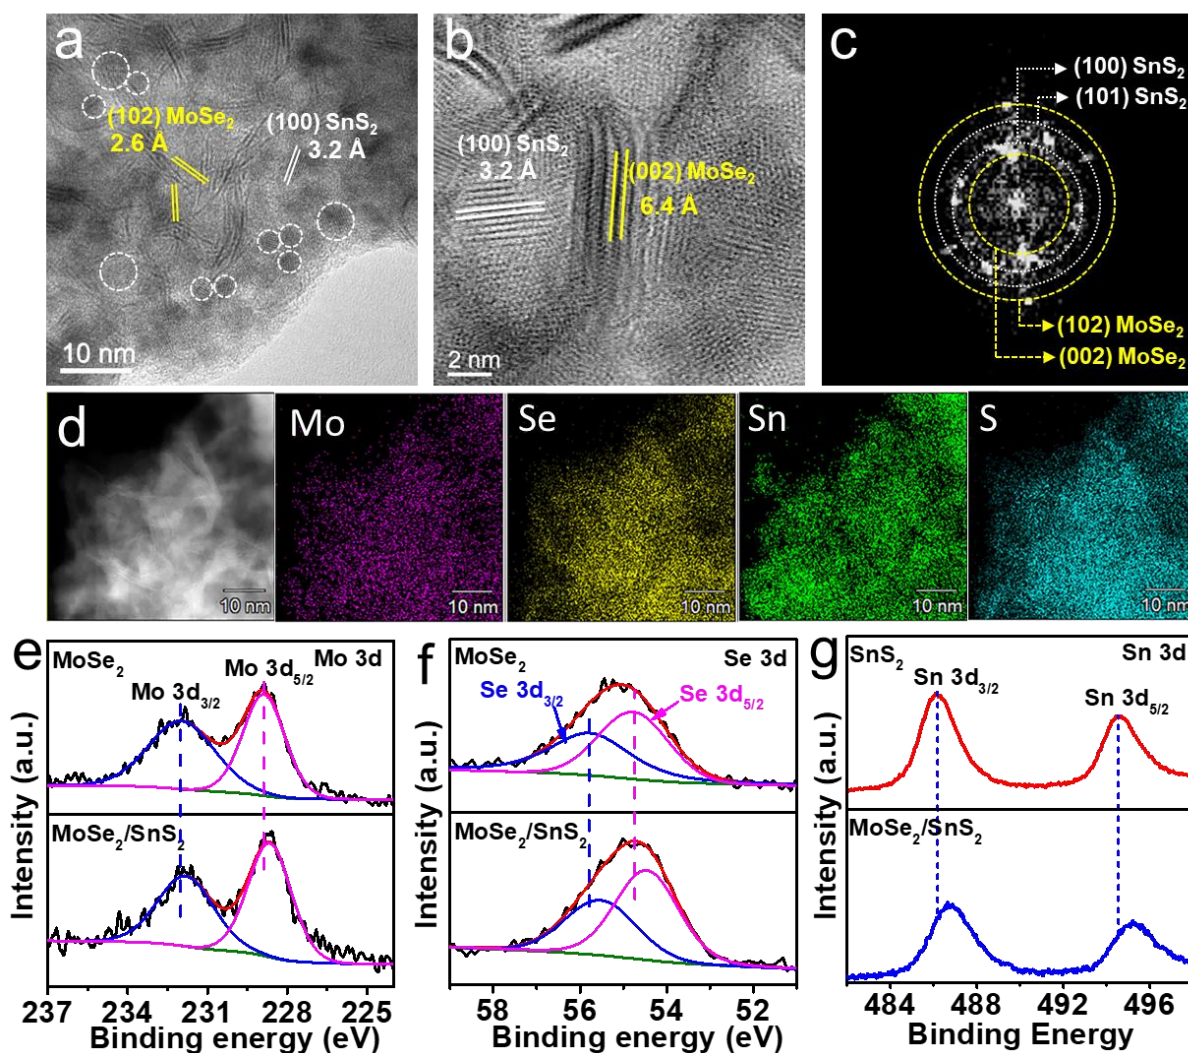

Figure 1. (a, b) TEM images and (c) the corresponding FFT pattern of MoSe₂/SnS₂-2.5 heterostructure; (d) STEM-EDS elemental mapping of Mo, Se, Sn, and S; XPS spectra of (e) Mo 3d, (f) Se 3d, and (g) Sn 3d.

The HER activities of the as-prepared MoSe₂ and MoSe₂/SnS₂ heterostructured catalysts were evaluated in 1 M KOH aqueous electrolyte in a standard three-electrode system. Figure 2a shows the polarization curves after 95% *iR* correction carried out at a scan rate of 5 mV s⁻¹. For the pure SnS₂, the linear sweep voltammetry (LSV) curve displays a weak current response, demonstrating its electrocatalytic inertness in alkaline media. The pure MoSe₂ needs an

overpotential of 367 mV to reach a current density of 10 mA cm^{-2} . Compared to MoSe_2 , all the $\text{MoSe}_2/\text{SnS}_2$ heterostructured catalysts show substantially enhanced catalytic activities. Specifically, the $\text{MoSe}_2/\text{SnS}_2\text{-2.5}$ heterostructured catalyst exhibits optimal HER activity and a much lower overpotential of 285 mV at 10 mA cm^{-2} (Figure 2b). Also, $\text{MoSe}_2/\text{SnS}_2\text{-2.5}$ shows the best mass activity (559 mA mg^{-1}) at 0.45 V among all the catalysts, which is superior to $\text{MoSe}_2/\text{SnS}_2\text{-1.5}$ (309 mA mg^{-1}), $\text{MoSe}_2/\text{SnS}_2\text{-5.0}$ (291 mA mg^{-1}), $\text{MoSe}_2/\text{SnS}_2\text{-10}$ (235 mA mg^{-1}), and pure MoSe_2 (147 mA mg^{-1}) (Figure 2c and the inset). These results indicate that SnS_2 plays a key role in promoting the HER kinetics of MoSe_2 in alkaline media. It is worth noting that the physically mixed sample with a molar ratio of $\text{MoSe}_2:\text{SnS}_2 = 2.5: 1$ ($\text{MoSe}_2+\text{SnS}_2\text{-2.5}$) delivers decreased geometric and mass activities (14 mA cm^{-2} and 87 mA mg^{-1} at 0.45 V), as compared to $\text{MoSe}_2/\text{SnS}_2\text{-2.5}$ and bare MoSe_2 (Figure S4, Supporting Information), revealing that the unique heterostructure morphology and interaction between MoSe_2 and SnS_2 are of great importance to the accelerated alkaline HER kinetics. Tafel slopes give further insights into the HER kinetics. As shown in Figure 2d, pure MoSe_2 shows a Tafel slope of 149 mV dec^{-1} , indicating that the kinetic rate-limiting step is the Volmer step, in which step water molecules dissociate into hydrogen intermediates and hydroxyls. Compared to MoSe_2 , the Tafel slope of $\text{MoSe}_2/\text{SnS}_2\text{-2.5}$ is reduced to 109 mV dec^{-1} , demonstrating that the HER kinetics are determined by the Volmer step and subsequent Heyrovsky step. The enhanced kinetics can be attributed to the accelerated water dissociation process (Volmer step).^[45]

Figure 2. (a) LSV polarization curves measured at a scan rate of 5 mV s⁻¹; (b) Overpotential at the current density of 10 mA cm⁻²; (c) LSV curves plotted based on MoSe₂ mass-normalized current density (inset: current densities at -0.45 V (vs. RHE)); (d) Tafel plots (potential vs. log(current density)) derived from LSV curves.

Turnover frequencies (TOFs) provide important insights in evaluating the intrinsic activity of HER catalysts. Generally, it is supposed that TOFs reflect the formation rate of hydrogen molecules per Mo atom during the HER process.^[49-50] Here, we identify the TOF value of MoSe₂/SnS₂ catalysts based on MoSe₂ which provides intrinsic active sites for the HER. Although the TOF calculation here employs the total Mo atoms in the electrode as the benchmark, which may not exactly reflect the performance of the MoSe₂/SnS₂ heterostructures, it provides a general comparison of the HER kinetics between MoSe₂ and MoSe₂/SnS₂ composites. The MoSe₂/SnS₂-2.5 achieves the highest TOF as compared with other samples (Figure 3a). Meanwhile, the electrochemically active surface area (ECSA), as another critical factor for estimating the activity of electrocatalysts, was determined by measuring the double-layer capacitance (C_{dl}) in the potential range of -0.1–0 V (vs. RHE) (Figure S5, Supporting

Information). As shown in Figure 3b, all the MoSe₂/SnS₂ heterostructured catalysts display larger C_{dl} values than that of pure MoSe₂, indicating that the introduction of SnS₂ endows the heterostructured catalysts with higher active site density.^[51] Moreover, the enhanced catalytic activity of MoSe₂/SnS₂ heterostructures was confirmed by electrochemical impedance spectroscopy (EIS). The Nyquist plots are well fitted to an equivalent circuit model (Figure S6, Supporting Information), which consists of electrolyte resistance (R_s), charge-transfer resistance (R_{ct}), and constant phase element (CPE). All the heterostructured catalysts show much lower R_{ct} than that of bare MoSe₂ (Table S2, Supporting Information), further demonstrating that the incorporation of SnS₂ is beneficial for accelerating the charge transfer and mass diffusion kinetics of MoSe₂/SnS₂ heterostructures under alkaline conditions.^[52]

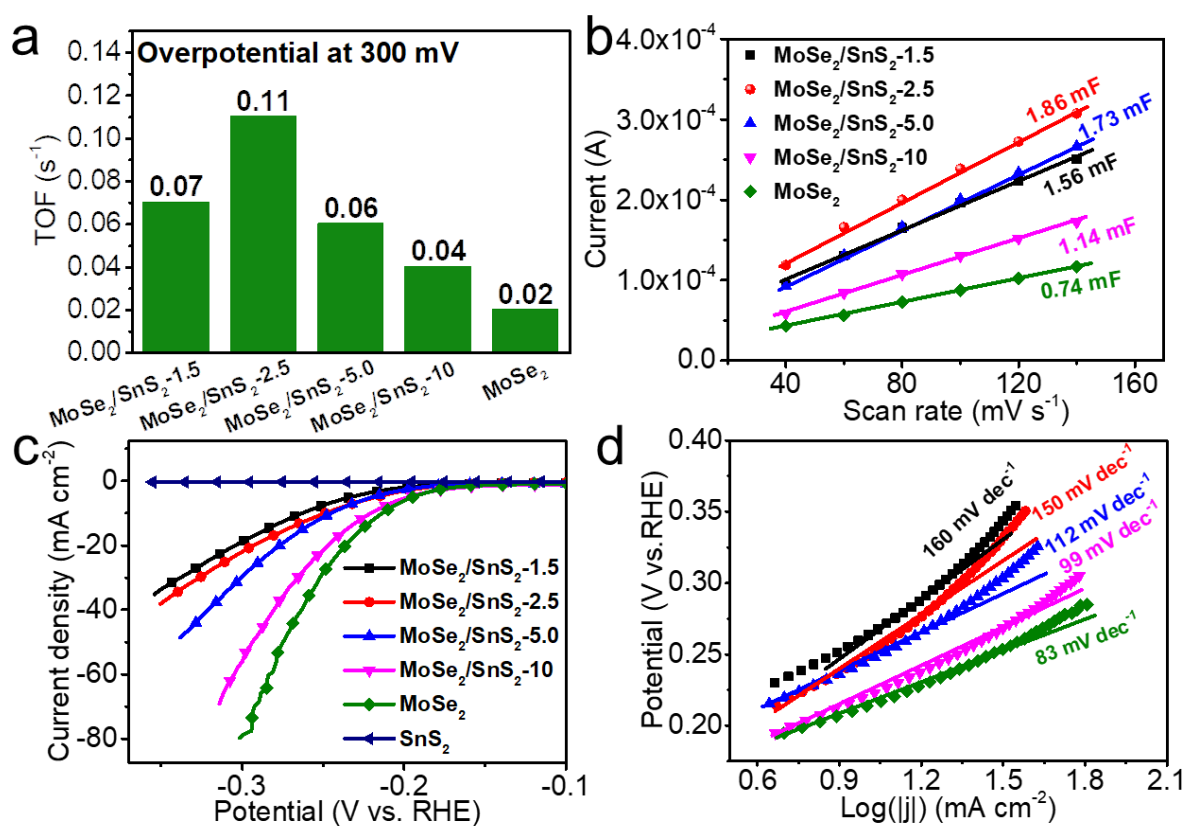

Figure 3. (a) TOFs of MoSe₂/SnS₂ heterostructures and pure MoSe₂ at the overpotential of 0.3 V (vs. RHE); (b) Current versus scan rate measured at 0 V (vs. RHE); (c) The LSV curves and (d) Tafel plots measured in 0.5 M H₂SO₄.

To further confirm the effect of incorporating SnS₂ on the enhanced alkaline HER activity of the MoSe₂/SnS₂ heterostructured catalysts, the acidic HER performances of MoSe₂/SnS₂ and bare MoSe₂ catalysts were tested in 0.5 M H₂SO₄ electrolyte. According to previously reported volcano plots, the HER kinetics of a catalyst in acidic conditions is strongly correlated with its hydrogen adsorption capability.^[53-54] In sharp contrast to the bare MoSe₂, all the MoSe₂/SnS₂ heterostructures show higher overpotentials with larger Tafel slopes (Figure 3c-d). The reduced acidic catalytic activities of the MoSe₂/SnS₂ heterostructured catalysts demonstrate that the introduction of SnS₂ had no positive effect on optimizing the hydrogen adsorption capability. It can be inferred that the enhanced alkaline HER activity of the MoSe₂/SnS₂ heterostructures can be mainly attributed to the accelerated water adsorption/dissociation process.

Basically, water adsorption takes place prior to water dissociation during the alkaline HER process. Therefore, to further verify the influence of SnS₂ quantum dots on the alkaline HER kinetics of MoSe₂, DFT calculations were conducted to determine the water adsorption energy (E_{ad}) of the basal planes and edges of pure MoSe₂, SnS₂, and MoSe₂/SnS₂ (Figure S7, Supporting Information). As shown in Figure 4a, the E_{ad} of the basal planes of MoSe₂ is -0.12 eV. After incorporating SnS₂, the E_{ad} of the basal planes of MoSe₂/SnS₂ decreases to -0.23 eV, suggesting that SnS₂ efficiently enhances the water adsorption capability on the basal planes of MoSe₂. The Mo edges, as the most stable sites for water adsorption, displays a lower E_{ad} (-0.82 eV) for MoSe₂/SnS₂ than that of MoSe₂ (0.71 eV) (Figure 4b). Meanwhile, the Se edges with 100% and 50% Se coverage (Se_{100-eg} and Se_{50-eg}) of MoSe₂/SnS₂ heterostructures also show decreased E_{ad} values relative to that of pure MoSe₂. These results clearly demonstrate that the incorporation of SnS₂ significantly enhances the water adsorption capability of MoSe₂ in the heterostructures, which is greatly beneficial to accelerating the subsequent water dissociation kinetics. In addition, the basal planes and edges of SnS₂ also show promising water

adsorption capability (Figure S8, Supporting Information), which can further improve the water adsorption and dissociating kinetics of the MoSe₂/SnS₂ heterostructures.

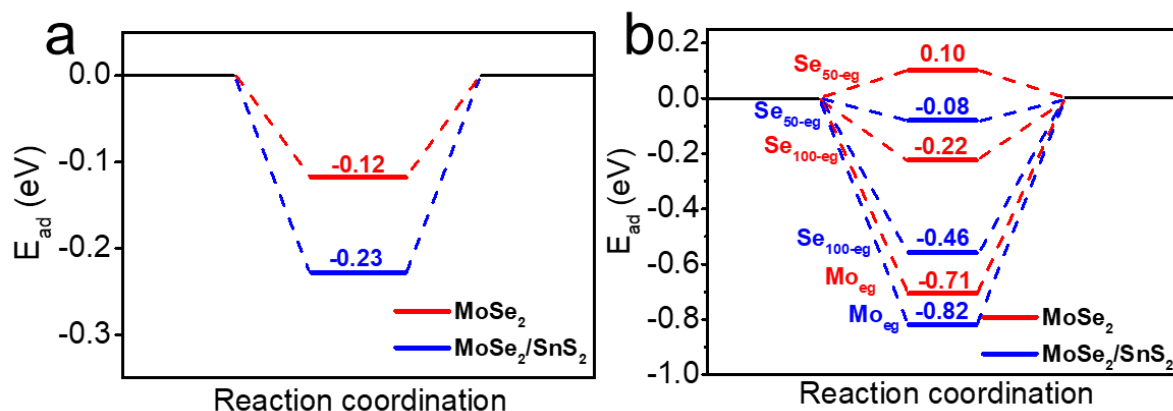

Figure 4. Water adsorption energy diagram of MoSe₂/SnS₂ and MoSe₂ (a) on the basal planes and (b) on the edge sites.

MoS₂/SnS₂ heterostructures with SnS₂ quantum dots decorated on the basal planes (Figure S9, Supporting Information), which were synthesized by a similar process to that for MoSe₂/SnS₂ heterostructures, were also evaluated as the catalysts for the alkaline HER. As shown in Figure S10a-b (Supporting Information), the alkaline HER activity of the heterostructured catalysts is also greatly enhanced after the introduction of SnS₂. The optimal MoS₂/SnS₂-2.5 catalyst delivers the lowest overpotential of 343 mV at 10 mA cm⁻² with a Tafel slope of 157 mV dec⁻¹, while pure MoS₂ has an overpotential of 419 mV at 10 mA cm⁻² with a Tafel slope of 216 mV dec⁻¹. Similar to the case of MoSe₂/SnS₂, the acidic HER performance of the MoS₂/SnS₂ heterostructures gets worse with increasing the content of inactive SnS₂ (Figure S11a-b, Supporting Information). These results demonstrate that decorating SnS₂ quantum dots on basal planes to construct heterostructures is a universal approach to promote the alkaline HER kinetics of molybdenum dichalcogenide-based catalysts.

4. Conclusion

In summary, molybdenum dichalcogenide heterostructures with SnS₂ quantum dots decorated on the basal planes were designed and synthesized as efficient alkaline HER electrocatalysts. The optimal MoSe₂/SnS₂ heterostructured catalyst delivered a substantially lower overpotential of 285 mV as compared with MoSe₂ (367 mV) at 10 mA cm⁻². The significant improvement in alkaline HER activity is mainly due to the accelerated water adsorption/dissociation kinetics. The DFT calculations reveal that the incorporation of SnS₂ can significantly improve the water adsorption capability of MoSe₂, which is critical for the subsequent water dissociation process. This work opens up a new direction for the development of efficient alkaline HER electrocatalysts by engineering heterostructures.
