High-performance room-temperature sodium-sulfur battery enabled by electrocatalytic sodium polysulfides full conversion

Abstract

© 2020 The Royal Society of Chemistry. Room-temperature sodium-sulfur (RT-Na-S) batteries are highly desirable for grid-scale stationary energy storage due to their low cost; however, short cycling stability caused by the incomplete conversion of sodium polysulfides is a major issue for their application. Herein, we introduce an effective sulfiphilic host, gold nanodots decorated on hierarchical N-doped carbon microspheres (CN/Au/S), to achieve completely reversible conversion reactions in the S cathode by electrocatalyzing the low-kinetics conversion of Na₂S₄ into NaS₂ (discharge process) or S (charge process). Besides, gold nanodots and N-doped carbon can increase the conductivity of the S cathode and provide strong polar-polar adsorption of sodium polysulfides to alleviate the shuttling effects. When serving as the cathode, the CN/Au/S composite can realize enhanced sulfur utilization, excellent cycling stability, and outstanding rate capability. This work deepens our understanding of the catalytic effect of gold atoms on sulfur molecules, opening a new avenue for cathode design and development of advanced RT-Na-S batteries.

Room-temperature sodium-sulfur (RT-Na-S) batteries are highly desirable for grid-scale stationary energy storage due to its low cost; however, short cycling stability caused by the incomplete conversion of sodium polysulfides is a major issue for their applications. Herein, we introduce an effective sulfiphilic host, gold nanodots decorated on hierarchical N-doped carbon microspheres (CN/Au/S), to achieve completely reversible conversion reactions in the S cathode through electrocatalyzing low-kinetics conversion Na_2S_4 into Na_2S (discharge process) or S (charge process). Besides, gold nanodots and N-doped carbon can increase the conductivity of the S cathode and provide strong polar-polar adsorption of sodium polysulfides to alleviate the shuttling effects. When serving as cathode, the CN/Au/S can realize enhanced sulfur utilization, excellent cycling stability, and outstanding rate capability. This work deepens our understanding of the catalytic effect of gold atoms on sulfur molecules, opening a new avenue for cathode design and the development of advanced RT-Na-S batteries.

Broader context

Developing large-scale energy storage systems is the top priority to integrate renewable but intermittent energy sources, such as solar and wind, into the electric grid. Room-temperature sodium-sulfur battery technology (RT-Na-S) is emerging as a very promising candidate with high energy density, low-cost, and large-scale stationary storage potential. The successful application of RT-Na-S will pave the way for shifting fossil fuels towards renewable energy system to power our economy in the long run. The low electroactivity of S and Na, however, results in incomplete reaction during charge/discharge process, leading to very low capacity. In our work, the introduction of gold nanocluster as an electrocatalyst can facilitate a completely reversible reaction between S and Na, demonstrating record high capacity and high rate performance. This work presents an appealing and competitive RT-Na-S battery with great potential for stationary storage applications.

Introduction

Efficient energy storage and conversion is essential to realize a sustainable society because it is the bridge between the grid and the intermittently available renewable energy sources^{1,2}. Among the various state-of-the-art energy storage devices, the room-temperature sodium-sulfur battery (RT-Na-S, Scheme 1a) has attracted particular attention due to its advantages of resource abundance (both sulfur and the sodium), nontoxicity, low cost, and high energy density¹⁻³. Unfortunately, the practical application of RT-Na-S has been retarded by several primary challenges, such as the low conductivity of sulfur and sodium sulfides, the huge volume variation of sulfur, and the low electroactivity of S and Na, as well as the dissolution of sodium polysulfide (NaPS) intermediates during cycling^{3,4}. The sluggish reactivity of S with Na causes an incomplete reduction of NaPS towards Na_2S (in discharge process) or S (in charge process), resulting in low sulfur utilization and reversible capacity⁵⁻⁸. The dissolution of polysulfide intermediates incurs shuttling effects and serious self-discharge and exacerbates capacity decay.

Therefore, the priority is to realize the confinement and conversion of the polysulfides in the cathode for a better RT-Na-S.

Recent research has gained progress in trapping NaPSs through physical and chemical anchoring strategies, based on the lessons from Li-S batteries⁹⁻¹⁴. Carbon nanostructures, the most studied sulfur host, have been scientifically devised with good electrical conductivity and appropriate pores to host sulfur particles and physically restrict NaPSs. Their nonpolar feature cannot produce effective interactions with the polar sodium polysulfides, however, and the corresponding S cathodes suffer from gradual capacity decay and poor rate capability. Recently developed polar hosts, such as metal dichalcogenides and metal nanoparticles, have demonstrated effective trapping of NaPSs through polar-polar interactions or strong chemical binding. Although the performance of RT-Na-S batteries was enhanced to some extent, these results are still far from expectation due to the sluggish reaction kinetics of Na_2S and NaPSs¹⁵. For example, Wang *et al.* discovered that the reversible reactions of RT-Na-S can only occur between S_8 and Na_2S_4 , based on *in situ* synchrotron X-ray diffraction (XRD), corresponding to a capacity of 418 mAh g⁻¹. This is only a quarter of the theoretical capacity of a Na-S battery when the Na-storage reaction is fully complete with Na_2S as the final discharge product (1672 mAh g⁻¹)¹³. Furthermore, the sluggish kinetics of this process not only causes an accumulation of soluble NaPSs in the cathode, which inevitably exacerbates the shuttle effect, but also results in the formation of large Na_2S particles, which are hard to recycle in the following

discharge-charge processes due to their harsh activation energy and poor electrical conductivity^{3,16}. Therefore, advanced strategies to improve the kinetics of NaPS conversion at the cathode need to be developed.

Various catalysts, such as platinum (Pt), cobalt (Co), and metal oxides/sulfides/nitrides, have been utilized to enhance the conversion rates of soluble lithium polysulfides to insoluble S (in the charge process) or Li₂S (in the discharge process)^{17–23}. Significantly, Arava *et al.* found that the use of Pt or Au as a catalyst could greatly enhance the reaction kinetics of the Li-S battery, because the strong non-chemisorbed gold-sulfur bond (2.5 eV) can effectively immobilize polysulfides without decreasing their reuse in the following cycle^{17,24}. Furthermore, gold nanocatalysts (with particle diameters below 10 nm) have been demonstrated to be astonishingly active towards electrochemical energy storage reactions, with examples such as Au-doped MnO₂ and nanoporous gold/MnO₂ films delivering significantly enhanced supercapacitor performance^{25,26}. This concept has been introduced into the RT-Na-S system to solve the same problems as in Li-S batteries^{15,16}. Nevertheless, electrochemical reversibility between sodium disulfide and sulfur is not achieved¹⁵. Nor have high rate RT-Na-S batteries been realized. Encouraged by the good conductivity and catalytic activity of gold atoms, in particular, since gold is more stable in electrochemical reactions than other transition metals, the introduction of gold into the RT-Na-S system is expected to effectively solve its sluggish kinetics problems.

Here we propose a new class of electrocatalytic gold nanodots as a catalyst for advanced RT-Na-S batteries. Based on *in situ* X-ray diffraction (XRD) patterns, cyclic voltammetry (CV), and theoretical

calculations, we find that gold nanocrystals can not only effectively trap the NaPSs via the strong gold-sulfur binding to alleviate the shuttle effect, but also greatly boost the conversion rates of NaPSs to improve the utilization of sulfur. In particular, gold nanodot-decorated carbon hosts could catalyze intermediate Na₂S₄ so that it is completely transformed into Na₂S in the discharge process and into S in the charge process, facilitating a completely reversible reaction between S and Na₂S. Consequently, the CN/Au/S cathode delivered excellent electrochemical performance, including high specific capacity (701 mAh g⁻¹ after the 110th cycle at 0.1 A g⁻¹), long cycling stability, and high rate capability (369 mAh g⁻¹ at 10 A g⁻¹ after 2000 cycles), demonstrating great potential for application in large-scale energy storage devices.

Results and discussion

Synthesis and Structure of the CN/Au/S Composite.

The formation procedures for CN/Au/S are schematically illustrated in Scheme 1b. First, uniform MnCO₃ microspheres (see Fig. S1) were heated in Ar atmosphere to decompose into porous Mn₂O₃ microspheres, in which Mn₂O₃ nanoparticles cross-linked to form the porous structure (see Fig. S2). Then resorcinol-formaldehyde resin and melamine as the carbon and nitrogen source, respectively, were used to coat a carbon layer on the surfaces of the cross-linked Mn₂O₃ nanoparticles as well as the whole microspheres. During carbonization in Ar atmosphere, the coated Mn₂O₃ composite can transform into MnO@N-doped carbon microspheres (denoted as

(b) Synthesis protocol for the CN/Au/S microspheres used in Na-S batteries.

Fig. 1. Morphology characterization of CN, CN/Au, and CN/Au/S samples. (a) SEM image of one broken CN microsphere. (b) STEM image of a CN/Au sample with particle size distribution of gold nanodots (inset). (c) Dark-field STEM image, (d) STEM image of CN/Au/S sample with particle size distribution of gold nanodots (inset). (e) Dark-field TEM image and corresponding elemental mapping images of CN/Au/S sample.

MnO@CN) (see Fig. S3). Hierarchical porous microspheres cross-linked by ultrathin N-doped carbon nanosheets (denoted as CN, see Fig. S4) were obtained by a facile HCl etching process. Afterwards, gold nanodots were loaded into the interior crosslinking carbon nanosheets of the CN, which is denoted as CN/Au. Followed by S encapsulation process, a CN/Au/S composite is prepared and expected to be a multifunctional S cathode in RT-Na-S batteries. The CN microspheres with interconnected interior 2D nanosheets can serve as micro reactors of S during charge/discharge processes, which can not only supply channels for electrolyte penetration and ion transport, but also can serve as reservoirs to alleviate dissolution of polysulfide intermediates via both physical and polar adsorption. More importantly, combined with increasing conductivity of S cathode and forming non-chemisorbed gold-sulfur bond, the ultrafine gold nanodots could provide effectively catalysis towards the conversion of sodium polysulfides, which will further boost the electrochemical performance of RT-Na-S batteries.

The morphological evolution of CN, CN/Au and CN/Au/S samples were shown in Fig. 1. A broken CN microsphere clearly displays cross-linked N-doped carbon nanosheets inside, and the thickness of the utmost spherical layer is ~ 10 nm (Fig. 1a). The low-magnification SEM images demonstrate the same morphology of CN and CN/Au samples, with a diameter around 2 μm (see Fig. S5). Specifically, scanning transmission electron microscopy (STEM) images illustrate that Au nanodots with mean size of 1.8 nm are uniformly distributed on the carbon nanosheets (both external and internal) (Fig. 1b and Fig. S5c). In contrast, the size of Au nanodots in CN/Au/S increases to 2.5–5.0 nm after sulfur loading, which is due to the strong absorption of Au nanodots for sulfur and agglomeration of Au nanodots during the heating process, (Fig. 1c–1e). Furthermore, corresponding elemental mapping demonstrates that sulfur is more likely to be distributed along the gold atoms rather than the CN backbones, indicating the strong absorption between Au and S.

The XRD patterns of CN/Au/S, CN/Au, CN, and S are shown in Fig. 2a. The narrow and sharp diffraction peaks demonstrate that pristine sulfur is in a high crystallization state, while the plain lines of CN and CN/Au manifest the amorphous nature of CN and the ultra-fine size of the Au nanodots. After encapsulating crystalline sulfur

into the CN (sample denoted as CN/S) and CN/Au, the sharp diffraction peaks of bulk crystalline sulfur almost completely disappear (see Fig. S6), demonstrating that the sulfur is highly dispersed in a low-molecular monolayered state inside the pores of the carbon host, which is agreement with the thermogravimetric analysis (TGA) results^{16,27}. As shown in Fig. 2b and Fig. S7, two thirds of the sulfur has evaporated at temperatures above 270 $^{\circ}\text{C}$, which indicates that most of the sulfur is confined in the micropores or encapsulated in the hollow spaces of the carbon matrix. Such a well dispersed state would greatly improve the electrical conductivity of the sulfur cathode^{13,16}. The sulfur content was confirmed by TGA to be 52.9 wt % for CN/S and 56.5 wt % for CN/Au/S. The slightly higher S ratio of CN/Au/S is likely due to the strong adsorption of ultrafine Au nanodots on S. The N_2 adsorption analysis for CN/Au the samples demonstrate Type IV isotherms along with H3 hysteresis loops, demonstrating the mesoporous structure of carbon microspheres (Fig. 2c). The CN/Au sample possesses a high surface area (766.4 m^2/g) and pore volume (0.66 cm^3/g), calculated based on the Brunauer-Emmett-Teller (BET) method, with the pore size distribution centered around 2.8 nm (inset to Fig. 2c). After sulfur loading, the surface area and pore volume sharply decreased to 71.4 m^2/g and 0.17 cm^3/g , respectively, owing to the sulfur filled into the pores of the CN/Au microspheres²⁷.

The chemical states of the CN, CN/Au, and CN/Au/S samples were further investigated by X-ray photoelectron spectroscopy (XPS). The N 1s spectrum of CN/Au/S and CN could be divided into two peaks at 399.4 and 400.6 eV, which are attributed to the binding energies of pyridinic and pyrrolic nitrogen (Fig. 2d and Fig. S8), respectively^{28–30}. The C 1s spectrum in Fig. S9 can be fitted as a sum of C–C (284.6 eV), C–N (286.2 eV), C–O (287.1 eV), and C=O (288.7 eV) bonds, which resulted from moisture in the sample as well as the native surface groups^{28–30}. The N heteroatom doping could effectively enhance the interaction between the carbon host and the lithium polysulfide guests in Li-S batteries through the introduction of polarity. Hence, it is expected that CN hosts with the N heteroatom

PAPER

doping could also facilitate a better anchoring effect on NaPSs in Na-S batteries³¹. After loading with Au and sulfur, the survey spectra of the CN/Au/S and CN/Au samples indicate the presence of Au and S elements without any changes in the C or N spectrum (see Fig. S10), because no chemical reaction takes place between the carbon matrix and the sulfur, indicating that there is mainly physical absorption between CN hosts and sulfur guests. Fig. 2e displays two typical peaks at 163.8 and 165.0 eV, corresponding to signals of S 2p_{3/2} and S 2p_{1/2}, owing to the spin-orbit split coupling. In addition, the peak located at 168.4 eV is assigned to sulfate with highly oxidized sulfur species³⁰. For the CN/Au sample, two typical peaks at 84.0 and 87.7 eV generated from Au 4f_{7/2} and Au 4f_{5/2}, respectively, are observed in Fig. 2f, demonstrating that chloroauric acid is completely reduced to Au⁽⁰⁾²⁹. As for the Au 4f spectrum in the CN/Au/S sample, the peaks with higher binding energy compared to the CN/Au sample indicate the strong adsorption between Au nanodots and sulfur guests, which is predicted to achieve strong interfacial interaction to trap sodium polysulfides during cycling, resulting in long cycling stability.

Electrochemical mechanism.

To understand the Na-S chemistry of CN/Au/S, *in situ* synchrotron XRD ($\lambda = 0.6888 \text{ \AA}$) (SXR) was performed to track the changes in the produced species during discharge/charge processes. As shown in Fig. 3, relatively strong characteristic peaks of sulfur are detected in the fresh cell because of the high resolution of SXR. In the initial discharge state (OCP (open-circuit potential) -1.8 V), the peaks of sulfur gradually become weak, while the peaks of polysulfides (Na₂S₅, JCPDS Card No. 44-0823) evolve and are growing in intensity (2.0-1.8 V). With the depth of discharge increasing (from 1.8 to 1.0 V), the peaks of Na₂S₅ gradually disappear; meanwhile, the peaks of Na₂S₄ (JCPDS Card No. 25-1112) start to show increasingly high intensity. When the cell is further discharged (0.8 V), only Na₂S is detected without any other sulfur species, indicating that Na₂S₄ has been totally converted into Na₂S (JCPDS Card No. 47-1698). This result is very different from that found in previous work (with only carbon used as the host material), where Na₂S₄ and Na₂S were both observed in SXR when the cell was discharged to 0.8 V, which is also consistent with our *ex situ* XRD investigation (see Fig. S11). When the CN/S sample was discharged to 0.8 V, Na₂S₄ and Na₂S were both detected. These results revealed that gold nanodots could effectively catalyze soluble Na₂S₄ into insoluble Na₂S in the discharge process.

PAPER

Fig. 3. Mechanism of CN/Au/S activity in RT-Na-S batteries. (a) *In situ* synchrotron XRD patterns of charged and discharged CN/Au/S sample in RT-Na-S batteries. (b) Contour plot of XRD patterns with selected theta for intermediate products. (c) Charge/discharge profiles of CN/Au/S and CN/S samples. CV curves for (d) CN/Au/S and (e) CN/S samples.

In the subsequent charge process, Na_2S_4 is observed in both *in situ* synchrotron XRD and *ex situ* XRD investigations (Fig. 3a, 3b and Fig. S11). More surprisingly, unlike single-atom cobalt catalyst, gold can catalyze Na_2S_4 to totally turn into S in the charge process (2.4–2.8 V). Without the Au catalysis, some irreversible Na_2S_4 can be detected in CN/S (see Fig. S11b). As shown in Fig. 3c, the different electrochemical reactions between CN/Au/S and CN/S can also be identified in the charge-discharge process. Although both samples displayed a plateau at about 2.25 V (in the discharge), the intensity for CN/Au/S is much stronger than that for CN/S, indicating that S is more fully converted into polysulfide in CN/Au/S than in CN/S, which reflected by the XRD patterns, as the peak intensity of NaPSs for CN/Au/S is stronger than for CN/S (see Fig. S11). The slopes between 2.25–1.8 V and 1.8–1.3 V are almost identical in the two samples, resulting in similar XRD patterns in this region. The biggest difference occurs at 1.3–0.8 V, where the slope of CN/Au/S is much longer than that of CN/S, corresponding to complete Na_2S_4 conversion to Na_2S in CN/Au/S and not in CN/S. The first discharge capacity of CN/Au/S is 2050 mAh g^{-1} , which is almost twice that of CN/S (1325 mAh g^{-1}).

These reaction discrepancies are also reflected in the CV curves. As shown in Fig. S12, the first cathodic peak attributed to the reduction of solid S to soluble long-chain polysulfides was found at 1.62 V for CN/Au/S and 1.6 V for CN/S, and the peak intensity of CN/Au/S is little stronger than that of CN/S. The peak corresponding to the sodiation of long-chain polysulfides to Na_2S_4 and then to Na_2S is centered at 1.01 V for CN/Au/S and 0.9 V for CN/S. This peak of CN/Au/S is reversible and shifts to 1.04 V in the following cycles (Fig. 3d). That of CN/S is not detected in following cycles, however, indicating that this reaction is not fully reversible in CN/S (Fig. 3e). In the charge process, two anodic peaks are observed in both samples. The first one is ascribed to the formation of Na_2S_4 and polysulfides, and the second one corresponds to oxidation of polysulfides to S. The second peak of CN/Au/S is much stronger than that of CN/S, which is in good agreement with the *in situ* SXRD and *ex situ* XRD data, where Na_2S_4 is completely changed into S by the Au catalyst in CN/Au/S.

Theoretical analysis.

To gain further insight on the electrochemical catalytic performance of Au in Na-S batteries, a theoretical investigation based on density functional theory (DFT) calculations was conducted. First, the adsorption energies of NaPSs (Na₂S₄, Na₂S₃, Na₂S₂, and Na₂S) on the nitrogen doped carbon surface and on Au decorated nitrogen doped carbon were investigated by DFT calculations (Fig. 4). The nanosheets in the CN sample are very thin and can be considered as assembled from several layers of graphene, and thus, single-layer graphene is applied in modeling the carbon substrate to compute the adsorption of NaPS molecules. We calculate their binding energy (E_{bind}) based on following relationships:

$$E_{\text{bind}} = E_{\text{sub+molecule}} - E_{\text{sub}} - E_{\text{molecule}}$$

where $E_{\text{sub+molecule}}$ is the total energy of the substrate with the molecule adsorbed, and E_{sub} and E_{molecule} are the total energies of the substrate and the isolated molecule, respectively. In general, negative binding energy demonstrates a positive adsorption capability, and the strength of the adsorption capability enhances as it becomes more negative. The calculated binding energies of S₈, Na₂S₄, Na₂S₃, Na₂S₂ and Na₂S are -0.03, -0.32, -0.78, -1.10 and -0.93 eV, respectively, for nitrogen doped carbon (Fig. 4a). After loaded with Au nanodots, the adsorption capability of the substrate greatly improves. As shown in Fig. 4a, the binding energies of S₈, Na₂S₄, Na₂S₃, Na₂S₂ and Na₂S are changed to -1.63, -2.97, -3.06, -3.52, and -3.94 eV, respectively, on the Au loaded carbon. This result demonstrates that the Au nanodots could remarkably strength the interaction between the NaPSs and the carbon host, which is favorable for the activity of the sulfur and effectively prevents shuttling of polysulfides.

Next, the S reaction pathways of both CN/S and CN/Au/S cathodes were studied. The overall reaction according to the reversible production of Na₂S from S₈ and Na was considered. In the discharge process, the first step is the reduction of S₈ to form Na₂S₄ by Na⁺, following which, Na₂S₄ experiences further reduction and, in turn, the formation of three intermediate NaPSs, that is, Na₂S₄, Na₂S₃, and Na₂S₂, resulting in the formation of Na₂S as the final product. The Gibbs free energies of the intermediates were calculated based on the above reactions on both CN and CN/Au supports, and the results displayed in Fig. 4b. The downhill path of the free energy from S₈ to Na₂S means spontaneous exothermic conversion, and all the conversions are spontaneous. This is more energetically favorable for CN/Au than for CN because of its lower Gibbs free energy values. Catalyzing the reduction of S₈ on CN/Au is crucial to drop the energy barrier and greatly enhance the battery performance. Therefore, these Au nanodots could effectively mitigate the shuttle effect by confining the polysulfides through their enhanced adsorption capability by polar-polar interactions. More importantly, Au nanodots could electrocatalyze sodium polysulfide conversion and improve the utilization of S, resulting in high specific capacity and energy density. These factors make CN/Au/S a promising cathode for high performance RT-Na-S batteries for large-scale energy storage.

Electrochemical performance evaluation.

Based on the mechanism analysis and theoretical predictions for the CN/Au/S sample in RT-Na-S batteries, the electrochemical performances of the synthesized samples were comprehensively investigated. Because of the catalytic effect of Au nanoparticles, the CN/Au/S delivers not only much higher specific capacity, but also much better rate properties than CN/S (Fig. 5, a and b). The CN/Au/S sample delivered an initial discharge capacity of 1967 mAh g⁻¹ and maintained 701 mAh g⁻¹ after the 110th cycle at 0.1 A g⁻¹. The high first discharge capacity may come from the decomposition of the electrolyte to form the solid electrolyte interphase (SEI) layer, as well as the side reactions between the electrolyte and the carbon host (see Fig. S13). In contrast, the CN/S only displays a discharge capacity of 1253 mAh g⁻¹ in the first cycle, and only keeps 330 mAh g⁻¹ after the 110th cycle at 0.1 A g⁻¹. Both samples show quick capacity fade in the initial cycles due to the loss of dissolved long-chain polysulfides, and they then attain relatively good cycling stability. The rate capability of CN/Au/S and CN/S was assessed at various current densities from 0.05 to 20 A g⁻¹ in the voltage window of 0.8 to 2.8 V and shown in Fig. 5b. At every stage of current density, CN/Au/S exhibits a higher capacity than CN/S. The CN/Au/S shows average capacities of 1010, 830, 755, 678, 599, 532, 414, 297, 230, and 181 mAh g⁻¹ at corresponding current densities of 0.05, 0.1, 0.2, 0.5, 1, 2, 5, 10, 15, and 20 A g⁻¹. More significantly, the capacity of CN/Au/S could revert to 934 mAh g⁻¹ when the current density returned to 0.05 A g⁻¹, demonstrating that the CN/Au/S can endure various current densities. The rate property of CN/Au/S is not only better than that of our synthesized CN/S, but also the previous reports on RT-Na-S (Fig. 5c)^{9,13,32,33-35}. To the best of our knowledge, such an extremely high rate performance of RT-Na-S batteries significantly exceeds those reported previously.

(e) Cycling performances of CN/S and CN/Au/S samples compared to references. (f) CV curves of CN/Au/S samples from 0.1 to 2.0 mV s⁻¹. (g) Charge-discharge curves at various current densities for the CN/Au/S sample. (h) Energy density (inset) and power density of CN/S and CN/Au/S samples.

It is indispensable but difficult to realize long-term cycling performance at high rate for current RT-Na-S batteries because of the poor sulfur reaction activity and severe polysulfide shuttle effect. Therefore, prolonged cycling of CN/Au/S was performed at the high rates of 2 A g⁻¹ and 10 A g⁻¹ (Fig. 5d and Fig. S14) to evaluate its long-term cycling stability. Impressively, the CN/Au/S can maintain a reversible capacity of 430 mAh g⁻¹ after 1000 cycles at 2 A g⁻¹, and 369 mAh g⁻¹ at 10 A g⁻¹ after 2000 cycles. This is the longest cycling lifespan among the present RT-Na-S batteries. Comparing the cycling performance to previous RT Na-S references, the CN/Au/S sample shows remarkable high capacity and stable cycling performance (Fig. 5e)^{2,9,12-14,32,33-39}. The enhanced performance of CN/Au/S is attributed to the unique material design strategy. The interconnected N-doped carbon nanosheets could serve as a highly conductive network for sulfur, electrons, and polysulfides.

Moreover, the outer carbon shell could confine the polysulfides, and the N-doping also effectively enhances the interaction between the carbon host and the polysulfides to limit the shuttle effect. Most importantly, the Au nanodots can catalyze polysulfide transformation, which improves the sulfur reactivity and utilization. Thus, the CN/Au/S is a very effective sulfur host for RT-Na-S batteries.

To further understand the Au catalytic effect and the outstanding electrochemical performance of CN/Au/S, the electrochemical impedance spectroscopy (EIS) and CV curves at various rates were collected. As shown in Fig. S15, CN/Au/S presents lower charge transfer resistance than CN/S, which may arise from the improved conductivity of Au nanodots. In addition, the charge transfer resistance gradually decreases during cycling, which demonstrates the dynamic activation process of the electrodes, enabling long cycling performance. This is different from the previous

reported RT-Na-S batteries, which exhibited an impedance increase owing to the accumulation of Na_2S in the cathode during cycling, causing a gradual capacity loss. It is worth pointing out that the cathodic peak around 2.4 V in CN/Au/S attributed to the transformation of Na_2S_4 to S can be observed in the CV curves at every rate (Fig. 5f), demonstrating that Au nanodots can catalyze polysulfide transformation even at high current density. In comparison, without the Au nanoparticles, the peak gradually disappears with increasing scan rate (see Fig. S16). In addition, the peak at 1.04 V (ascribed to the conversion of Na_2S_4 to Na_2S) of CN/Au/S is also stronger than that of CN/S, which means that the Au nanoparticles are still working in the cathodic process. This process is further confirmed by the fact that the CN/Au/S sample presents smaller polarization than the CN/S at higher current densities (Fig. 5g and Fig. S17). It should be noted that the gravimetric energy/power densities are affected by the specific capacity, and thus the CN/Au/S sample delivers higher gravimetric energy/power densities than CN/S (Fig. 5h). Therefore, the CN/Au/S cathode is a reasonable choice for RT-Na-S batteries.

Conclusions

In summary, we describe an emerging high-performance RT-Na-S battery in which N-doped carbon microspheres decorated with gold nanodots serve as an effective sulfur host. The cross-linking inside channels permits mass transport and electrolyte infiltration. The nitrogen doping and gold nanodots can enhance the adsorption between the polysulfides and carbon via polar-polar interactions. Furthermore, the thick outside shell can physically confine the reactions inside of the sphere, which can relieve the polysulfide shuttle effect. More importantly, the gold nanodots play a very critical role as an electrocatalyst, which enables the intermediate Na_2S_4 to be completely transformed into the final product Na_2S , contributing to enhanced reactivity of the sulfur cathode and high accessible capacity. Thus, the resultant CN/Au/S cathode presents long cycling stability and high rate capacity (701 mAh g^{-1} after 110 cycles at a 0.1 A g^{-1} and 369 mAh g^{-1} after 2000 cycles at 10 A g^{-1}). This work not only provides a deeper understanding of catalyzing the activity of sulfur molecules in RT-Na-S batteries, but also opens new opportunities to enable high-performance RT-Na-S batteries for grid-scale stationary energy storage systems.

Author Contributions

G.Y. and S.D. supervised the project. N.W., Y.W. and Z.B. designed and performed the experiments. Z.X. designed and performed the DFT calculations. Y.W. help with the *in-situ* synchrotron XRD. Z.F., X.Z., X.X. and Y.D. helped with the experiment and discussion section. N.W. and Z.B. wrote the manuscript. Y.W., S.D. and G.Y. revised the manuscript. All authors were involved in the discussion of data analysis and commented on the manuscript. N.W., Y.W. and Z.B. have contributed equally to this work.

Conflicts of interest

There are no conflicts to declare.

Acknowledgements

G. Y. acknowledges the funding support from US Department of Energy, Office of Science, Basic Energy Sciences, under Award DE-SC0019019. S.D. acknowledges the financial support from the Australian Research Council (ARC) through Discovery Projects (DP160102627), a Linkage Project (LP160100273), and Discovery Early Career Researcher Award (DE170100928). The authors thank Dr. Tania Silver, Ningyan Cheng and Dr. Li Wang for helpful discussions.
