Estimating the atmospheric concentration of Criegee intermediates and their possible interference in a FAGE-LIF instrument

Abstract
We analysed the extensive dataset from the HUMPPA-COPEC 2010 and the HOPE 2012 field campaigns in the boreal forest and rural environments of Finland and Germany, respectively, and estimated the abundance of stabilised Criegee intermediates (SCIs) in the lower troposphere. Based on laboratory tests, we propose that the background OH signal observed in our IPI-LIF-FAGE instrument during the aforementioned campaigns is caused at least partially by SCIs. This hypothesis is based on observed correlations with temperature and with concentrations of unsaturated volatile organic compounds and ozone. Just like SCIs, the background OH concentration can be removed through the addition of sulfur dioxide. SCIs also add to the previously underestimated production rate of sulfuric acid. An average estimate of the SCI concentration of \( \sim 5.0 \times 10^4 \) molecules cm\(^{-3} \) (with an order of magnitude uncertainty) is calculated for the two environments. This implies a very low ambient concentration of SCIs, though, over the boreal forest, significant for the conversion of SO\(_2\) into H\(_2\)SO\(_4\). The large uncertainties in these calculations, owing to the many unknowns in the chemistry of Criegee intermediates, emphasise the need to better understand these processes and their potential effect on the self-cleaning capacity of the atmosphere.

Abstract. We analysed the extensive dataset from the HUMPPA-COPEC 2010 and the HOPE 2012 field campaigns in the boreal forest and rural environments of Finland and Germany, respectively, and estimated the abundance of stabilised Criegee intermediates (SCIs) in the lower troposphere. Based on laboratory tests, we propose that the background OH signal observed in our IPI-LIF-FAGE instrument during the aforementioned campaigns is caused at least partially by SCIs. This hypothesis is based on observed correlations with temperature and with concentrations of unsaturated volatile organic compounds and ozone. Just like SCIs, the background OH concentration can be removed through the addition of sulfur dioxide. SCIs also add to the previously underestimated production rate of sulfuric acid. An average estimate of the SCI concentration of $\sim 5.0 \times 10^4$ molecules cm$^{-3}$ (with an order of magnitude uncertainty) is calculated for the two environments. This implies a very low ambient concentration of SCIs, though, over the boreal forest, significant for the conversion of SO$_2$ into H$_2$SO$_4$. The large uncertainties in these calculations, owing to the many unknowns in the chemistry of Criegee intermediates, emphasise the need to better understand these processes and their potential effect on the self-cleaning capacity of the atmosphere.

1 Introduction

Criegee intermediates (CIs), or carbonyl oxides, are formed during the ozonolysis of unsaturated organic compounds (Criegee, 1975; Johnson and Marston, 2008; Donahue et al., 2011): in the gas phase, ozone attaches to a double bond, forming a primary ozonide (POZ) that quickly decomposes forming a Criegee intermediate and a carbonyl compound. The CIs can exist as thermally stabilised CIs (SCIs) or as chemically activated CIs (Kroll et al., 2001; Drozd et al., 2011), where the chemically activated CIs have high energy content and in the atmosphere either undergo unimolecular
decomposition or are stabilised by collisional energy loss forming SCIs.

For many decades the chemistry of Criegee intermediates was investigated with both theoretical and indirect experimental studies as reviewed in detail by Johnson and Marston (2008), Vereecken and Francisco (2012), and Vereecken et al. (2015). During the last few years, numerous experimental studies specifically on stabilised Criegee intermediates have been performed following their first detection by Welz et al. (2012). Many laboratories have now detected SCIs with various techniques (Berndt et al., 2012; Mauldin III et al., 2012; Ouyang et al., 2013; Taatjes et al., 2013; Ahrens et al., 2014; Buras et al., 2014; Liu et al., 2014a; Sheps et al., 2014; Novelli et al., 2014b; Stone et al., 2014; Chhantyal-Pun et al., 2015; Lee, 2015; Newland et al., 2015a; Fang et al., 2016a; Smith et al., 2016) and have confirmed that they are very reactive towards many atmospheric trace gases. Currently, the most studied Criegee intermediates are formaldehyde oxide, CH$_2$OO; acetaldehyde oxide, CH$_3$CHOO (syn and anti, i.e. with the outer oxygen pointing towards or away from an alkyl group, respectively); and acetone oxide, (CH$_3$)$_2$COO.

The importance of stabilised Criegee intermediates as oxidants in the atmosphere depends on the rate coefficient of their reaction with water vapour as the latter is ubiquitously present in relatively high concentrations in the boundary layer (between $10^{16}$ and $10^{17}$ molecules cm$^{-3}$). The rate of this reaction strongly depends on the CI conformation (Aplincourt and Ruiz-López, 2000; Tobias and Ziemann, 2001; Ryzhkov and Ariya, 2003; Kuwata et al., 2010; Anglada et al., 2011; Anglada and Sole, 2016; Chen et al., 2016; Lin et al., 2016; Long et al., 2016) and until now the rate coefficient has been measured for anti-CH$_2$CHOO (Taatjes et al., 2013; Sheps et al., 2014), while lower limits have been determined for CH$_2$OO (Stone et al., 2014), syn-CH$_3$CHOO (Taatjes et al., 2013; Sheps et al., 2014), and (CH$_3$)$_2$COO (Huang et al., 2015; Newland et al., 2015b). The uncertainties in these rate coefficients make it difficult to estimate the importance of Criegee intermediates and the impact they may have as oxidants in the atmosphere. Additionally, recent studies (Berndt et al., 2014b; Chao et al., 2015; Lewis et al., 2015; Smith et al., 2015; Lin et al., 2016) have showed that the reaction between CH$_2$OO and water dimers (present in the ppmv range in the atmosphere; Shilling et al., 2011) is faster than the reaction with water vapour, in agreement with the several theoretical studies (Ryzhkov and Ariya, 2004; Chen et al., 2016; Lin et al., 2016) which indicate the reaction with water dimers to be between 400 and 35000 times faster than the reaction with water vapour depending on the conformers. Another important reaction of SCIs that depends on the SCI conformation is their unimolecular decomposition. The decomposition rate and product formed depend on the SCI conformer structure. anti-SCIs are likely to isomerise via the ester channel forming an ester or an acid as the final product, while syn-SCIs will form a vinyl hydroperoxide (VHP) which promptly decomposes forming hydroxyl radicals (OH) and a vinoxy radical (Paulson et al., 1999; Johnson and Marston, 2008; Drozd and Donahue, 2011; Vereecken and Francisco, 2012; Kidwell et al., 2016). Larger and more complex conformers such as hetero-substituted or cyclic structures are subject to additional unimolecular rearrangements (Vereecken and Francisco, 2012). On the unimolecular decomposition rates and products few experimental data are available (Horie et al., 1997, 1999; Fenske et al., 2000a; Novelli et al., 2014b; Kidwell et al., 2016; Fang et al., 2016a; Smith et al., 2016), but more is available from theoretical studies explicitly focusing on the path followed by different conformers (Anglada et al., 1996; Aplincourt and Ruiz-López, 2000; Kroll et al., 2001; Zhang and Zhang, 2002; Nguyen et al., 2009b; Kuwata et al., 2010).

Most of the experimental and theoretical information described above refers to the smaller conformers. These compounds are likely to be formed relatively efficiently in the atmosphere as they can originate from any unsaturated compound with a terminal double bond, but they do not represent the entire Criegee intermediate population.

As SCIs were found to react quickly with many trace gases, various model studies were performed on the impact SCIs have as oxidants in the atmosphere (Vereecken et al., 2012; Boy et al., 2013; Percival et al., 2013; Pierce et al., 2013; Sarwar et al., 2013, 2014; Novelli et al., 2014b; Vereecken et al., 2014). Some of these studies focused in particular on the possible impact that SCIs might have on the formation of sulfuric acid (H$_2$SO$_4$) in the gas phase, following Mauldin III et al. (2012), who suggested that Criegee intermediates are the missing SO$_2$ oxidant needed to close the sulfuric acid budget over a boreal forest. This is supported by theoretical and laboratory studies that have determined a rate coefficient between SCIs and sulfur dioxide (SO$_2$) of the order of $10^{-11}$ cm$^3$ molecule$^{-1}$ s$^{-1}$ (Aplincourt and Ruiz-López, 2000; Jiang et al., 2010; Kurtein et al., 2011; Vereecken et al., 2012; Welz et al., 2012; Taatjes et al., 2013; Liu et al., 2014b; Sheps et al., 2014; Stone et al., 2014). As the main atmospherically relevant oxidiser of SO$_2$ in the gas phase is the OH radical with a rather slow rate coefficient at ambient temperature and pressure of $2 \times 10^{-12}$ cm$^3$ molecule$^{-1}$ s$^{-1}$ (Atkinson et al., 2004), the high rate coefficient for SO$_2$ oxidation would allow SCIs to have a significant impact on the H$_2$SO$_4$ formation even if present in small concentrations. The model studies have shown that, depending on the environment, SCIs can have a potentially important impact on H$_2$SO$_4$ formation. All these studies are affected by large uncertainties and many simplifications are used for coping with the paucity of data on the reac-
tions of specific SCIs with various trace gas species, on the speciation of SCIs, and on the steady-state concentration of SCIs in the troposphere. Until now no direct or reproducible indirect method has been able to determine the steady-state concentration of SCIs in the lower troposphere.

In this paper, we firstly estimate the concentration of SCIs in the lower troposphere, based on the data collected during the HUMPPA-COPEC 2010 campaign (Williams et al., 2011) in a boreal forest in Finland and the HOPE 2012 campaign in rural southern Germany. The budget of SCIs is analysed using four different approaches: (1) based on an unexplained H$_2$SO$_4$ production rate (Mauldin III et al., 2012); (2) from the measured concentrations of unsaturated volatile organic compounds (VOCs); (3) from the observed OH reactivity (Nölscher et al., 2012); and (4) from an unexplained production rate of OH (Hens et al., 2014). Secondly, we present measurements obtained using our inlet pre-injector laser-induced fluorescence assay by gas expansion technique (IPI-LIF-FAGE) (Novelli et al., 2014a) during the HUMPPA-COPEC 2010 and the HOPE 2012 campaigns. A recent laboratory study performed with the same instrumental setup showed that the IPI-LIF-FAGE system is sensitive to the detection of the OH formed from unimolecular decomposition of SCIs (Novelli et al., 2014b). Building on this study, the background OH (OH$_{bg}$) (Novelli et al., 2014a) measured during the two field campaigns is investigated in comparison with many other trace gases in order to assess whether the observations in controlled conditions are transferable to the ambient conditions.

2 Instrumentation and field sites

2.1 IPI-LIF-FAGE description

A comprehensive description of the IPI-LIF-FAGE ground-based instrument, HORUS (Hydroxyl Radical Measurement Unit based on fluorescence Spectroscopy), is given by Novelli et al. (2014a) and only some important features of the instrument are highlighted here. The IPI-LIF-FAGE instrument consists of the inlet pre-injector (IPI), the inlet and detection system, the laser system, the vacuum system, and the instrument control and data acquisition unit. The air is drawn through a critical orifice into a low-pressure region (~300–500 Pa) where OH molecules are selectively excited by pulsed UV light around 308 nm. The light is generated at a pulse repetition frequency of 3 kHz by a Nd:YAG pumped, pulsed, tunable dye laser system and is directed into a multipass "White cell" making 32 passes through the detection volume (White, 1942). The air sample intersects the laser beam and the fluorescence signal from the excited OH molecules is detected using a gated micro-channel plate (MCP) detector. The IPI, situated in front of the instrument inlet, is used to measure a chemical zero to correct for possible internal OH signal generation. An OH scavenger (propene) is added to the sample air 5 cm in front of the inlet pinhole in a concentration that allows a known, high proportion of atmospheric OH to be scavenged (~90%). The OH scavenger is added every 2 min so that the instrument measures a total OH signal (OH$_{tot}$) when the OH scavenger is not injected and a background OH signal (OH$_{bg}$) when the OH scavenger is injected. The difference between these two signals yields the atmospheric OH concentration (OH$_{atm}$). The efficiency of this technique for measuring OH with this particular LIF-FAGE instrument is described together with the IPI characterisation in Novelli et al. (2014a). The OH calibration of the HORUS instrument is obtained via the production of a known amount of OH and hydroperoxyl radicals (HO$_2$) from the photolysis of water at 185 nm using a mercury lamp. A more detailed description of the instrument calibration is reported by Martinez et al. (2010) and Hens et al. (2014). A calibration factor for the background OH signal observed by the HORUS instrument is currently not available. Therefore, this signal will be discussed and plotted in OH fluorescence counts per second measured by the MCP, normalised by the laser power and corrected for quenching and sensitivity changes towards the detection of OH. The sensitivity of the instrument towards the OH radical is affected by alignment of the white cell, optical transmission of the components, sensitivity of the MCP, water vapour, internal pressure, and internal temperature (Martinez et al., 2010). These factors affect the sensitivity of HORUS towards the background OH in a similar manner as they mainly impact the sensitivity of the instrument to the detection of OH.

We hypothesise that the OH$_{bg}$ is formed chemically within the IPI-LIF-FAGE instrument. Laser-induced production of OH radicals was thoroughly tested in the laboratory and in the field (Novelli et al., 2014a), showing that this background OH signal is not induced by the laser beam from double pulsing, nor from air stagnating in the detection cell. By changing the laser power, no quadratic dependency of the OH$_{bg}$ was observed even at night time, when the contribution of the OH$_{bg}$ to the OH$_{tot}$ measured by the instrument is highest (Novelli et al., 2014a). In addition, during the HUMPPA-COPEC 2010 and HOPE 2012 campaigns, the correlation coefficient of the OH$_{bg}$ with the laser power was $R = 0.002$ and $R = 0.2$, respectively.

In contrast, ozonolysis of alkenes performed during laboratory tests showed that the IPI-LIF-FAGE instrument is sensitive to the OH formed from unimolecular decomposition of SCIs within the low-pressure section of the instrument (Novelli et al., 2014b).

Recently, most of the LIF-FAGE instruments have been augmented with the titration of OH$_{atm}$ in different environments to determine their background (Amédro, 2012; Mao et al., 2012; Griffith et al., 2013, 2016; Woodward-Massey et al., 2015; Tan et al., 2017). Some of these instruments showed the presence of an unknown interference (Mao et al., 2012; Griffith et al., 2013; Tan et al., 2017), while for others no clear conclusions were drawn (Amédro, 2012;
Woodward-Massey et al., 2015). In addition, laboratory studies (Fuchs et al., 2016; Griffith et al., 2016) have shown similarity with what was observed with the IPI-LIF-FAGE during experiments of ozonolysis of alkenes, although the origin of the OH signal was not uniquely attributed to a particular mechanism.

Our hypothesis is that the OH$_{bg}$ measured in ambient air with the IPI-LIF-FAGE at least partially originates from unimolecular decomposition of SCIs. Section 4 describes the observed behaviour of the signal during the campaigns and its relationship to other observed chemical tracers and discusses whether this is compatible with our hypothesis.

2.2 Measurement site and ancillary instrumentation

We present measurements from two sites, a boreal forest site in Finland and a rural site in southern Germany. The HUMPPA-COPEC 2010 (Hyytiälä United Measurements of Photochemistry and Particles in Air – Comprehensive Organic Precursor Emission and Concentration study) campaign took place during summer 2010 at the SMEAR II station in Hyytiälä, Finland (61°51′N, 24°17′E; 181 m a.s.l.) in a boreal forest dominated by Scots pines (Pinus silvestris L.). The site hosts continuous measurements of several trace gases and meteorological parameters as well as aerosol particle concentrations, size distributions, and composition (Junninen et al., 2009). Further details and a more complete description of the site, the instrumentation, and the meteorological conditions during the campaign can be found in Williams et al. (2011) and Hens et al. (2014). A brief description of the instruments used in this study is given here. Ozone was measured by a UV photometric gas analyser (model 49, Thermo Electron Corporation). A gas chromatograph (GC, Agilent Technologies 6890A) coupled to a mass-selective detector (MS, Agilent Technologies MSD 5973 inert) was used for the measurements of biogenic volatile organic compounds (BVOCs) (Yassaa et al., 2012). The total OH reactivity was measured by the comparative reactivity method (CRM) (Sinha et al., 2008) for two different heights, one within and one above the canopy (18 and 24 m, respectively) (Nölscher et al., 2012). CRM uses an in situ kinetics experiment to measure the OH reactivity based on the competitive scavenging of OH by a reference gas (pyrrole) and atmospheric OH reactants. The overall uncertainty of the method during deployment was 16%, with a limit of detection of 3.0 s$^{-1}$ (Hens et al., 2014). Sulfur dioxide (SO$_2$) concentration was measured with a fluorescence analyser (model 43S, Thermo 20 Environmental Instruments Inc.). Aerosol number size distributions between 3.0 and 950 nm were measured with a differential mobility particle sizer (DMPS) (Aalto et al., 2001). The size distributions were used for calculating the loss rate of gas-phase sulfuric acid via condensation sink (CS) with the method presented by Kulmala et al. (2001). Sulfuric acid (H$_2$SO$_4$) and OH radical concentrations were measured on the ground with a chemical ionisation mass spectrometer (CIMS; Petaja et al., 2009). Time series of the measured trace gases are available in the study from Nölscher et al. (2012) and Hens et al. (2014). The average concentrations and their 1σ variability are listed in Tables 1 and S2 in the Supplement. For the first period of the campaign, between 27 and 31 July, the IPI-LIF-FAGE instrument was run on the ground side by side with the CIMS. On 2 August the IPI-LIF-FAGE instrument was moved to the top of the HUMPPA tower above the canopy and measured there for the remainder of the campaign (12 August). The data are therefore separated into ground and tower periods.

The HOPE 2012 (Hohenpeißenberg Photochemistry Experiment) campaign was conducted during the summer of 2012 at the Meteorological Observatory in Hohenpeissenberg, Bavaria, Germany (47°48’N, 11°2’E). The observatory is a Global Atmospheric Watch (GAW) station operated by the German Meteorological Service (DWD) and is located at an altitude of 985 m a.s.l. and about 300 m above the surrounding terrain, mainly consisting of meadows and coniferous forests. More information about the site can be found in Handisides et al. (2003). Ozone was measured by UV absorption with a TEI 49C (Thermo Electron Corporation, Environmental Instruments) (Gilge et al., 2010). Non-methane hydrocarbons were measured with a GC–flame ionisation detection (FID) system (series 3600CX, Varian, Walnut Creek, CA, USA) (Plass-Dülmer et al., 2002). BVOCs were detected using a GC (Agilent 6890) with a FID running in parallel with a MS (Agilent Technologies MSD 5975 inertXL) described by Hoerger et al. (2015). Photolysis frequencies (J(NO$_2$) and J(O$_3$D)) were measured next to the IPI-LIF-FAGE with a set of filter radiometers (Handisides et al., 2003). The OH reactivity was measured with two instruments for a short period of time from 10 until 18 July. One method was the CRM and the same instrument was used as during the HUMPPA-COPEC 2010 campaign. The second method was a new application of the DWD CIMS instrument (Berresheim et al., 2000) which also measured H$_2$SO$_4$ and OH radicals. As the data will be used only in a qualitative way for the current study, a very short description of this novel technique is given here and details will be presented in the Supplement. For the first period of the campaign, between 27 and 31 July, the IPI-LIF-FAGE instrument was run on the ground side by side with the CIMS. On 2 August the IPI-LIF-FAGE instrument was moved to the top of the HUMPPA tower above the canopy and measured there for the remainder of the campaign (12 August). The data are therefore separated into ground and tower periods.

a future publication. With the CIMS instrument, OH radicals are measured by converting them into H$_2$SO$_4$ after reaction with SO$_2$ in a chemical reactor and subtraction of a corresponding background after scavenging the OH with propane (Berresheim et al., 2000). A second SO$_2$ titration zone was used 15 cm (or 140 ms) downstream of the first injection to determine the OH decay from OH radicals generated in the UV-calibration zone immediately upstream of the first titration. The difference between these two titration zones in two consecutive 2.5 min intervals allows the determination of the OH decay, after correcting for ambient OH and wall losses. The uncertainty is estimated at ±2.0 s$^{-1}$ and the limit of detection is 2.0 s$^{-1}$. SO$_2$ concentration was measured with a fluorescence analyser and aerosol size distributions were measured and used to calculate the loss rate of gas-phase sulfuric acid due to CS formed by existing aerosol surface via the method presented by Birmili et al. (2003). Time series of the measured trace gases are available in Fig. S1 in the Supplement. The average concentrations and their 1σ variability are listed in Tables 1 and 2.

*Note: $k_{\text{SCI}+\text{SO}_2} = 3.3 \times 10^{-11}$ cm$^3$ molecule$^{-1}$ s$^{-1}$. $k_{\text{SCI}+\text{SO}_2} = 5.0 \times 10^{-11}$ cm$^3$ molecule$^{-1}$ s$^{-1}$. $P_{\text{CS}} = 1.0 \times 10^9$ molecules cm$^{-3}$ s. $P_{\text{unexplained}} = 2.0 \times 10^9$ molecules cm$^{-3}$ s. 1 ppbv = 2.5 × 10$^10$ molecules cm$^{-3}$ at 295 K and 1013 hPa. n/a: not applicable.*

The rate coefficient between OH and SO$_2$ at standard pressure is (2.0 ± 0.1) × 10$^{-12}$ T/300 s$^{-1}$ cm$^3$ molecule$^{-1}$ (Atkinson et al., 2004). The rate coefficient of SCIs with SO$_2$ was determined by several groups at (3.3 ± 2.0) × 10$^{-11}$ cm$^3$ molecule$^{-1}$ s$^{-1}$ (Welz et al., 2012; Taatjes et al., 2013; Liu et al., 2014b; Sheps et al., 2014; Stone et al., 2014; Chhantyal-Pun et al., 2015; Newland et al., 2015a, b; Foreman et al., 2016; Zhu et al., 2016). An earlier, lower value of ~5.0 × 10$^{-13}$ cm$^3$ molecule$^{-1}$ s$^{-1}$ (Mauldin III et al., 2012; Berndt et al., 2012) appears to be hard to reconcile with the remaining literature, as extensively discussed in the Supplement.

Equation (2) allows for the calculation of a time series of SCIs (Fig. S2), yielding an average [SCI] = (2.3 ± 2.0) × 10$^4$ molecules cm$^{-3}$. A similar estimate of the SCI time series was derived for the HOPE 2012 campaign (Fig. S3). These time series are discussed in more detail in the Supplement; for the estimation of atmospheric SCIs here we focus mostly on the overall concentration.

The H$_2$SO$_4$ concentration during this campaign can be mainly explained by the reaction between OH and SO$_2$. Figure 1 shows the correlation between the total production rate of H$_2$SO$_4$ (P(H$_2$SO$_4$)tot) calculated from the product of measured H$_2$SO$_4$ and the condensation sink, as well as the production rate of H$_2$SO$_4$ from the reaction of OH and SO$_2$. The linear regression following the method of York et al. (2004) yields a slope of 0.9 ± 0.02 with a negligible intercept (57 ± 7.0 molecules cm$^{-3}$ s$^{-1}$). It should be noted that the H$_2$SO$_4$ budget for the HOPE 2012 campaign is nearly closed, such that the moderate fluctuations on the source data (CS, [OH], etc.) lead to very large relative uncertainties of the small missing H$_2$SO$_4$ production term.
and concomitantly the time series for the SCI concentration (Fig. S3) shows extreme variability reflecting this noise on the source data. On average, the [SCI] obtained is low, \((2.0 \pm 3.0) \times 10^6\) molecules cm\(^{-3}\), with no values in the time series exceeding \(10^6\) molecules cm\(^{-3}\).

Repeating the above analysis using the low \(k_{\text{SCI+SO}_2}\) value of Mauldin III et al. (2012) and Berndt et al. (2014) yields concentrations of \((1.6 \pm 2.0) \times 10^6\) and \((1.0 \pm 3.0) \times 10^6\) molecules cm\(^{-3}\) for the HUMPPA-COPEC and HOPE campaigns, respectively. It is interesting to note that both values estimated with the fast and low \(k_{\text{SCI+SO}_2}\) rate coefficient are in agreement with the concentrations calculated from measured VOCs and \(O_3\) for polluted and pristine environments, \(1.9 \times 10^6\) and \(4.5 \times 10^6\) molecules cm\(^{-3}\) respectively, from a previous study (Welz et al., 2012).

3.2 Measured unsaturated VOCs

Another method to estimate the SCI concentration is based on their production and loss processes. In a forest SCIs are expected to be formed from the ozonolysis of unsaturated BVOCs. It is possible to calculate an average steady-state concentration for SCIs using the following equation

\[
[\text{SCI}] = \sum_i \left( \frac{k_{\text{VOC}_i+O_3} \times [\text{VOC}_i] \times Y_{\text{SCI}}}{L_{\text{SCI}_{\text{syn}}}^i} \right) \times [O_3],
\]

where \(k_{\text{VOC}_i+O_3}\) is the rate coefficient between the VOC\(i\) and ozone (Table S2), \(Y_{\text{SCI}}\) is the yield of SCIs in the ozonolysis reaction, and \(L_{\text{SCI}_{\text{syn}}}^i\) is the total loss of syn-SCI. We assume \([\text{SCI}] \approx [\text{SCI}_{\text{syn}}]\) following the model described by Novelli et al. (2014b), which accounts for many possible losses of SCIs, including the reaction with water dimers and unimolecular decomposition. The latter study suggests that anti-acetaldehyde oxide and formaldehyde oxide react quickly with water and water dimers and that their contributions can be neglected. A yield of SCI formation \(Y_{\text{SCI}}\) of 0.4 was estimated based on the data by Hasson et al. (2001).

The steady-state concentration of SCIs for the HUMPPA-COPEC 2010 campaign was calculated using the measured data for \([O_3]\) and \([\text{VOC}_i]\), and an average value of \(40\ \text{s}^{-1}\) (Novelli et al., 2014b) for \(L_{\text{SCI}_{\text{syn}}}^i\) as this value was found to be rather constant and mainly dependent on the unimolecular decomposition rate of the SCIs. Equation (3) allows for the calculation of a time series of SCIs (Fig. S4) yielding an average \([\text{SCI}]\) of \((5.0 \pm 4.0) \times 10^3\) molecules cm\(^{-3}\). These time series are discussed in more detail in the supporting information; for the estimation of atmospheric SCIs here we focus mostly on the overall concentration.

During the HOPE 2012 campaign a larger number of unsaturated organic trace gases, both anthropogenic and biogenic, were measured (Table S1). For \(Y_{\text{SCI}}\) the same value of 0.4 was used, while for \(L_{\text{SCI}_{\text{syn}}}^i\) the value of 32 s\(^{-1}\), obtained from the model described by Novelli et al. (2014b) for the rural European environment, was used. Using these values in Eq. (3) results in \([\text{SCI}] = (7.0 \pm 6.0) \times 10^3\) molecules cm\(^{-3}\), obtained as an average of the SCI time series (Fig. S5). It should be noted that recent work on the unimolecular decomposition (Fang et al., 2016b; Long et al., 2016; Smith et al., 2016) yields loss rates significantly faster than used here; this implies that the [SCI] obtained here could be an overestimate.

3.3 OH reactivity

During HUMPPA-COPEC 2010, between 27 July and 12 August, an average OH reactivity of \(R = 9.0 \pm 7.6\ \text{s}^{-1}\) was measured. On average, the majority of the measured OH reactivity \((R_{\text{unex}} = 7.4 \pm 7.4\ \text{s}^{-1}\), i.e. 80%) was not accounted for by the measured organic and inorganic trace gases (Fig. S6). Biogenic emissions comprised up to \(~10\%\) of the total measured OH reactivity and up to half of the calculated OH reactivity (Fig. S6). As the measurement site was located in a pristine forest environment, affected only little by anthropogenic emissions (Williams et al., 2011), it is likely that a large fraction of the unexplained OH reactivity was formed by unmeasured primary emissions by the vegetation and secondary products of oxidation. By assuming that the unmeasured VOCs are unsaturated, and by using a lumped rate coefficient, \(k_{\text{VOC}_i+OH}\) between OH and the fraction of unspeciated VOCs of \(7.0 \times 10^{-11}\) cm\(^3\) molecule\(^{-1}\) s\(^{-1}\), typical for an OH addition to a carbon–carbon double bond (Atkinson et al., 2004; Peeters et al., 2007), it is possible to estimate the concentration \([\text{VOC}_{\text{unknown}}]\) of VOCs that...
of (7.0 ± 1.0) × 10^{11} \text{ molecules cm}^{-3} \) is obtained. These values are substituted into Eq. (3) and a lumped rate coefficient \( k \times 7.0 \times 10^{-17} \text{ molecules cm}^{-3} \) is used for reaction of \([\text{VOC}_\text{unknown}])\) with \([\text{O}_3]\) at time \(t\). This \(k\) value is based on the rate coefficient of the measured VOCs with \(\text{O}_3\) weighted with their abundance (Table S1). The same \(Y_{\text{SCI}}\) and \(L_{\text{SCI, syn}}\), of 0.4 and 40 s\(^{-1}\), respectively, were used as described in Sect. 3.2. With these values, a time series of SCIs (Fig. S7) with an average of \(\sim (1.0 \pm 1.0) \times 10^8 \text{ molecules cm}^{-3}\) is obtained. To this SCI concentration estimate, we add the SCIs formed from the measured unsaturated VOCs, \([\text{SCI]} = (5.0 \pm 4.0) \times 10^8 \text{ molecules cm}^{-3}\), to obtain the total SCIs across all VOCs. As this estimate requires assumptions for the rate coefficient between \([\text{VOC}_\text{unknown}]\) and \(\text{O}_3\) and \(\text{OH}\), a sensitivity study probing the upper and lower bounds of this estimate is described in the Supplement. The time series are discussed in more detail in the Supplement; for the estimation of atmospheric SCIs here we focus mostly on the overall concentration.

During the HOPE 2012 campaign the total \(\text{OH}\) reactivity was on average 3.5 ± 3.0 s\(^{-1}\). Using the measured trace gas concentrations it is possible to calculate the expected \(\text{OH}\) reactivity (Fig. S8). Table S2 lists all the species included in the calculation of the \(\text{OH}\) reactivity with their rate coefficient with \(\text{OH}\). An average value of 2.7 ± 0.7 s\(^{-1}\) was calculated. Figure S8 shows that half of the measured \(\text{OH}\) reactivity can be explained by methane, carbonyl compounds (mainly acetaldehyde and propanal), and inorganic compounds which were present in higher concentrations compared to the HUMPPA-COPEC 2010 campaign (Table S2). On average, 24% of the measured \(\text{OH}\) reactivity remains unexplained by the measured trace gases. In contrast to the HUMPPA-COPEC 2010 campaign, in HOPE 2012 a more complete speciation of VOCs was measured (Table S1) and the site was influenced by relatively fresh anthropogenic emissions. With the extensive VOC speciation available, the reactivity budget can virtually be closed, but any remaining unexplained \(\text{OH}\) reactivity could still be due to unmeasured VOCs. The time series for this unexplained \(\text{OH}\) reactivity, typically about \(\sim 1\) s\(^{-1}\), shows very large variability as it reflects the statistical noise of the small difference between measured and calculated \(\text{OH}\) reactivities, both of which are associated with variability. The resulting [SCI] time series (Fig. S9) is also highly variable, and yields a low average SCI concentration of (2.0 ± 1.5) \times 10^8 \text{ molecules cm}^{-3}, with no values exceeding 6.0 \times 10^8 \text{ molecules cm}^{-3}.

The total of SCIs is then obtained by summing the SCIs predicted from the measured VOCs and from the unexplained \(\text{OH}\) reactivity, leading to a total SCI concentration of (7.0 ± 6.0) \times 10^7 \text{ molecules cm}^{-3}.

3.4 Unexplained \(\text{OH}\) production rate

During the HUMPPA-COPEC 2010 campaign, the comprehensive measurements (Williams et al., 2011) allowed the calculation of a detailed \(\text{OH}\) budget (Hens et al., 2014). Most of the \(\text{OH}\) production during daytime is due to photolysis of \(\text{O}_3\) and recycling of HO\(_2\) back to \(\text{OH}\) via reactions with \(\text{NO}\) and \(\text{O}_3\). This result holds for both high \((R > 15\text{ s}^{-1})\) and low \((R \leq 15\text{ s}^{-1})\) \(\text{OH}\) reactivity episodes during the campaign. While the \(\text{OH}\) budget can be closed during daytime \((J(\text{O}^1\text{D}) > 3.0 \times 10^{-6}\text{ s}^{-1})\) for low \(\text{OH}\) reactivity periods, during periods with high \(\text{OH}\) reactivity there was a large unexplained production rate of \(\text{OH}\), \(P_{\text{OH}}^{\text{unexplained}} = (2.0 ± 0.7) \times 10^7 \text{ molecules cm}^{-3} \text{ s}^{-1}\), which can thus be surmised to originate from VOC chemistry. In addition, for both periods, during night time \((J(\text{O}^1\text{D}) \leq 3.0 \times 10^{-6}\text{ s}^{-1})\), the IPI-LIF-FAGE and the CIMS instruments both measured non-negligible \(\text{OH}\) concentrations (Hens et al., 2014) where most of the \(\text{OH}\) production was from unknown sources \((P_{\text{OH}}^{\text{unexplained}} = 1.0 ± 0.9 \times 10^6 \text{ molecules cm}^{-3} \text{ s}^{-1} \ (1\sigma))\) and \((P_{\text{OH}}^{\text{unexplained}} = 1.7 ± 0.7 \times 10^7 \text{ molecules cm}^{-3} \text{ s}^{-1} \ (1\sigma))\) for low and high \(\text{OH}\) reactivity, respectively. Our hypothesis is that ozonolysis of VOCs could represent the missing \(\text{OH}\) source. Indeed, formation of \(\text{OH}\) from oxidation of unsaturated VOCs has been shown to be an important source of \(\text{OH}\) in winter, indoors and during night time (Paulson and Orlando, 1996; Geyer et al., 2003; Ren et al., 2003; Heard et al., 2004; Harrison et al., 2006; Johnson and Marston, 2008; Shallcross et al., 2014). As \(\text{OH}\) formation from ozonolysis proceeds through Criegee intermediates (Fig. 2), we can attempt to estimate a SCI concentration from the \(\text{OH}\) budget. First, we estimate from the unexplained \(\text{OH}\) production \(P_{\text{OH}}^{\text{unexplained}}\) a so-called unexplained \(\text{O}_3\) reactivity, \(\sum (k_{\text{VOC} + \text{O}_3} \times [\text{VOC}_{\text{unidentified}}])\), assuming a certain yield of \(\text{OH}\) from ozonolysis of unsaturated VOCs. Next, we estimate a yield of SCIs based on available literature data, and finally we combine both to estimate the SCI concentration required to close the \(\text{OH}\) budget. In contrast to the previous estimates, an average value is obtained for the SCIs, and not a time series, as we start from the average \(P_{\text{OH}}^{\text{unexplained}},\) as reported in Hens et al. (2014).

Assuming that all unexplained \(\text{OH}\) production, \(P_{\text{OH}}^{\text{unexplained}},\) comes from VOC ozonolysis with a certain OH yield \(Y_{\text{OH}},\) we obtain

\[
P_{\text{OH}}^{\text{unexplained}} = \frac{k_{\text{VOC} + \text{O}_3} \times [\text{VOC}_{\text{unidentified}}] \times [\text{O}_3] \times Y_{\text{OH}}}{k_{\text{SCI}} \times [\text{SCI}]^{1.7}} \tag{5}
\]

where \([\text{VOC}_{\text{unidentified}}]\) includes the VOCs not considered in the \(\text{OH}\) budget performed by Hens et al. (2014), i.e. the VOCs causing the unknown OH reactivity discussed above. The average total \(\text{OH}\) yield from ozonolysis, \(Y_{\text{OH}},\) is estimated at about 0.6 based on observed \(\text{OH}\) yields from the

by the decomposition of chemically activated CI
ysis occurs through two channels (Fig. 2): prompt formation
literature (Atkinson et al., 2006). OH formation from ozonol-
Figure 2. Schematic representation of the formation of OH from
Schematic overview of the estimated steady-state concentration of SCIs ([SCI$_{ss}$, molecules cm$^{-3}$]) observed during the HUMPPA-COPEC 2010 and HOPE 2012 campaigns. For both campaigns the SCI estimate is based on the unsaturated VOC concentration measured, [VOC], and the H$_2$SO$_4$ budget using different SCI + SO$_2$ rate coefficients ($k_{SCI + SO_2}$ in cm$^3$ molecule$^{-1}$ s$^{-1}$). In addition, during the HUMPPA-COPEC campaign SCIs can be calculated from the unexplained OH reactivity, $R_{unexplained}$, and unexplained OH production, $P_{OH}^{unexplained}$. See main text for more details (Sect. 3).

for syn-CH$_3$CHOO, and where the steady-state concentration of the SCI$_{syn}$, [SCI$_{syn}$], is determined by the ratio of the formation processes and the sum $L_{SCI_{syn}}$ of the loss processes already defined above:

$$[SCI_{syn}] = \frac{k_{voc + O_3} \times [VOC_{unidentified}] \times [O_3] \times Y_{SCI} \times Y_{syn}}{L_{SCI_{syn}}}$$

Merging the above equations, expressing the measured OH production from unknown sources as the sum of direct OH production from CI* and indirect from SCI$_{syn}$, we obtain

$$P_{OH}^{unexplained} = k_{voc + O_3} \times [VOC_{unidentified}] \times [O_3] \times \left( Y_{CI^*} + Y_{SCI} \times Y_{syn} \times \frac{k_{OH}}{L_{SCI_{syn}}^3} \right).$$

The measured $P_{OH}^{unexplained}$ and [O$_3$] and the estimates of the other parameters allow us to calculate the factor $k_{voc + O_3} \times [VOC_{unidentified}]$. Substituting this factor into Eq. (6) yields an estimate of the steady-state concentration of SCI$_{syn}$. With a value for $P_{OH}^{unexplained}$ of $1.0 \times 10^3$ molecules cm$^{-3}$ s$^{-1}$ as observed for low-reactivity episodes and at night during HUMPPA, a steady-state concentration of SCI$_{syn}$ of $2.0 \pm 2.0 \times 10^3$ molecules cm$^{-3}$ is calculated. For high-reactivity episodes during HUMPPA-COPEC 2010, the missing $P_{OH}^{unexplained}$ of $2.0 \times 10^3$ molecules cm$^{-3}$ s$^{-1}$ results in a SCI concentration

The production of OH from SCI$_{syn}$ formed from VOCs not included in the OH budget is then $k_{OH} \times [SCI_{syn}]$, where we estimate $k_{OH} \approx 20$ s$^{-1}$ as measured by Novelli et al. (2014b)
of \((4.0 \pm 4.0) \times 10^5\) molecules cm\(^{-3}\). To obtain the total SCI concentration, we then need to add the non-OH-producing SCIs. Here we assume that these are mostly anti-SCIs or \(H_2CO\), both of which react rather quickly with \(H_2O\) or \((H_2O)_2\) (Taatjes et al., 2013; Chao et al., 2015; Lewis et al., 2015), and that their contribution can be neglected. We thus obtain that \([SCI] \approx [SCI_{syn}]\). To this we add the SCI concentration calculated from the measured unsaturated VOCs (Sect. 3.2), \((5.0 \pm 4.0) \times 10^3\) molecules cm\(^{-3}\), to obtain the SCIs formed from all VOCs.

For HOPE 2012 it is difficult to accurately derive an OH budget due to the lack of information on the HONO concentration, which can represent an important primary source of OH. A detailed analysis of the OH production and loss during the campaign thus requires a detailed model study to derive HONO concentrations, which is outside the scope of this paper. Hence, an estimate on the SCIs from a possible missing OH production rate during the HOPE 2012 campaign is not included here.

Equation (7), for a given set of yields, unimolecular decomposition rates, and SCI losses, allows the estimate of the relative contribution of SCIs and \(Cl^+\) to the total production rate of OH from the ozonolysis of VOCs. With the yields considered in this study and for a unimolecular decomposition rate of SCIs into OH of 20 s\(^{-1}\), the SCIs would contribute up to 12% to the total formation of OH from ozonolysis of VOCs in both environments. This indicates that the SCIs do not have a large impact in the production of OH radicals and at the same time emphasises how important a realistic estimate of VOC concentration is for modelling the OH radical as already underlined by Hens et al. (2014).

### 3.5 Robustness of the [SCI] estimates

Figure 3 summarises the steady-state concentration of SCIs calculated on the basis of the \(H_2SO_4\) budget, the measured unsaturated VOC concentration and OH reactivity \((R)\), and the OH budget for the HUMPPA-COPEC 2010 and HOPE 2012 campaigns. By considering the lower and the highest values estimated from the measured VOCs and from the missing \(H_2SO_4\) oxidant for both campaigns, respectively, the steady-state concentration of SCIs is calculated to be between \(5.0 \times 10^3\) and \(2.0 \times 10^6\) molecules cm\(^{-3}\) for the boreal forest environment during the HUMPPA-COPEC 2010 campaign and between \(7.0 \times 10^3\) and \(1.0 \times 10^6\) molecules cm\(^{-3}\) for rural Germany during the HOPE 2012 campaign (Table 2). The SCI concentrations calculated using these approaches represent a best-effort estimate made for the environments studied here based on the available data; due to the many uncertainties related to the chemistry of SCIs both in production and loss processes, these estimates span about 2 orders of magnitude.

The estimate of the SCI concentration from the sulfuric acid budgets relies on the rate of oxidation of \(SO_2\) to \(H_2SO_4\). As indicated in Sect. 3.1, two significantly different rate coefficients for the reaction of SCIs with \(SO_2\) are currently available. One coefficient is high, \(3.3 \pm 2.0 \times 10^{-11}\) cm\(^3\) molecule\(^{-1}\) s\(^{-1}\), while the other is several orders of magnitude lower, \(5.0 \times 10^{-13}\) cm\(^3\) molecule\(^{-1}\) s\(^{-1}\). Justifications of the differences in the values due to the diverse procedures, i.e. direct detection of SCI + \(SO_2\) for the high rate coefficient and detection of \(H_2SO_4\) for the lower one, are difficult, while recent measurements tend to agree with the highest value. This casts doubts on the highest obtained SCI concentrations of \(\sim 10^6\) molecules cm\(^{-3}\). In addition, the remaining three estimates strongly depend on the yield of SCIs, \(k\) VOC + \(O_3\), and \(L_{SCI_{syn}}\). Among these, the parameter with the highest uncertainty is the loss rate of syn-SCIs, \(L_{SCI_{syn}}\), as it is based on relatively few studies, which report large differences between the observations. In this study, values of \(40\) s\(^{-1}\) and of \(32\) s\(^{-1}\), based on previous model analysis (Novelli et al., 2014b), for the HUMPPA-COPEC 2010 and HOPE 2012 campaigns, respectively, were used. Recent work (Smith et al., 2016; Fang et al., 2016a; Long et al., 2016) suggests a faster unimolecular decomposition rate for the acetone oxide Criegee intermediate, exceeding \(10^6\) s\(^{-1}\) in ambient conditions. It is currently not clear whether this rate applies to more substituted SCIs as formed from monoterpenes, but the use of these higher decomposition rate in the model by Novelli et al. (2014b) would result in a total \(L_{SCI_{syn}}\) of \(\sim 110\) s\(^{-1}\). This loss rate would decrease the estimated SCI concentration by almost a factor of 3, closer to the lower estimates not exceeding \(10^5\) molecules cm\(^{-3}\); this also casts doubt on the highest estimates given in Fig. 3. Therefore, an average estimated SCI concentration of about \(5 \times 10^4\) molecules cm\(^{-3}\), with an uncertainty of an order of magnitude, is considered more appropriate for both campaigns.

### 4 The source of the OH background signal

In this section we examine the background OH signal, \(OH_{bg}\) (Novelli et al., 2014b) measured during the two field campaigns discussed in the previous sections. In particular, we examine whether this signal is consistent with the SCI chemistry and concentrations indicated above.

#### 4.1 Correlation of \(OH_{bg}\) with temperature

The time series of the background OH signal measured during the HUMPPA-COPEC 2010 and HOPE 2012 campaigns are shown together with temperature and \(J(O(\Delta))\) values in Fig. 4. Increases and decreases in the \(OH_{bg}\) signal follow the temperature changes. During the HUMPPA-COPEC 2010 campaign the \(OH_{bg}\) shows a strong correlation with temperature (Fig. 5) with a correlation coefficient \(R = 0.8\) for the exponential fit. The exponential dependency with temperature is in agreement with data shown by Di Carlo et al. (2004) for the unexplained OH reactivity and indicates...
that the species responsible for the OH\textsubscript{bg} strongly correlate with emission of biogenic VOCs (BVOCs) such as monoterpenes and sesquiterpenes, which have been shown to also exponentially depend on temperature (Guenther et al., 1993; Duhl et al., 2008; Hakola et al., 2003). This suggests that OH\textsubscript{bg} is directly related to BVOC chemistry. The relationship between OH\textsubscript{bg} and temperature during the HOPE 2012 campaign is less obvious. It is possible to observe a weakly exponential correlation between the two ($R = 0.51$, Fig. S10) but there is very large scatter in the data. It is worthwhile to underline the differences between the two environments. The forest in Finland is essentially pristine and BVOC-dominated, while in southern Germany a large fraction of non-biogenic VOCs was observed. The lack of a clear exponential correlation between OH\textsubscript{bg} and temperature during the HOPE 2012 campaign could suggest different precursors or a different origin for the OH\textsubscript{bg} within the two environments.

During both campaigns a negligible correlation, $R = 0.2$, was observed between background OH and J(O\textsuperscript{1}D). This suggests that the OH\textsubscript{bg} does not primarily originate from photolabile species.

4.2 Correlation of OH\textsubscript{bg} with unexplained OH reactivity

As described in Sect. 3.3, during the HUMPPA-COPEC 2010 campaign high average OH reactivity was observed ($\sim 9 \text{ s}^{-1}$), of which between 60 and 90\% cannot be explained by the loss processes calculated from the measured species (Nölscher et al., 2012). A large unexplained fraction of the reactivity has often been observed, especially in forested environments (Di Carlo et al., 2004; Sinha et al., 2008; Edwards et al., 2013), indicating a large fraction of undetected BVOCs and/or secondary oxidation products. The OH\textsubscript{bg} shows some correlation with the measured unexplained OH reactivity at 18 m, for the period on the ground ($R = 0.4$), and the measured unexplained OH reactivity at 24 m, for the period on the tower ($R = 0.4$) (Fig. 6). If we consider only night-time data, i.e. J(O\textsuperscript{1}D) $\leq 3.0 \times 10^{-6} \text{ s}^{-1}$ (Hens et al., 2014), we obtain better agreement between the two datasets for both ground and tower periods. During the night a large fraction of observed OH production (Sect. 3.4) could not be explained, which can tentatively be attributed to formation of OH from ozonolysis of BVOCs, suggesting that the background OH could be related to such a process. Correlation between the OH\textsubscript{bg} and the OH reactivity was also observed in a study by Mao et al. (2012) in a ponderosa pine plantation (California, Sierra Nevada) dominated by isoprene, where even higher OH reactivity was observed ($\sim 20 \text{ s}^{-1}$).

During the HOPE 2012 campaign such a correlation with the unexplained OH reactivity was not observed ($R = 0.1$). The OH reactivity was, on average, 3 times less than during the campaign in Finland and, as shown in Sect. 3.3, 50\% can be explained by reaction of OH with methane, formaldehyde, acetaldehyde, inorganic compounds (NO\textsubscript{x}, SO\textsubscript{2}, CO) and anthropogenic VOCs. On average only 17\% of the OH reactivity is caused by reaction of OH with BVOCs in this environment (Fig. S8), dropping to 10\% during the night. The unexplained OH reactivity is not influenced by distinguishing between day and night-time data, suggesting a small contribution of non-measured BVOCs. As this site is more strongly affected by anthropogenic emissions (Table S2) compared to the site in Finland, assuming that the OH\textsubscript{bg} originates from
BVOC-driven chemistry, a lack of correlation between OH$_{bg}$ and OH reactivity can be expected.

4.3 Correlation of OH$_{bg}$ with ozonolysis chemistry

During the HUMPPA-COPEC 2010 campaign a high correlation with O$_3$, $R = 0.7$ (Fig. S11), indicates that background OH likely originates from ozonolysis processes. A comparison of background OH with the product of ozone concentration, measured unsaturated VOC concentration and their ozonolysis rate coefficient does not show the same relationship. No correlation ($R = 0.05$) is found by using the measured BVOC concentrations (Table S1). As most of the OH reactivity remains unexplained, with measured BVOCs comprising less than 10% of the measured OH reactivity (Fig. S6, Table S2), the lack of correlation could suggest that the VOCs responsible for the formation of SCIs detected by the HORUS instrument are likely part of the large fraction of unmeasured species to which a correlation was reported in the previous section.

During HOPE 2012 a weak correlation was observed between background OH and ozone ($R = 0.5$, Fig. S12).

This campaign, from 10 July to 19 August 2012, encompasses a time period, from 1 to 3 August 2012, which was characterised by tree cutting in the vicinity of the measurement site. During this period a significantly larger fraction of unexplained OH reactivity, up to 40% (Fig. S13), was observed. The relative contribution of measured BVOCs and inorganic compounds did not change, while the presence of unidentified BVOCs emitted from the trees as a result of the stress induced on the plants from the cutting activity caused the larger fraction of unexplained reactivity. Figure 7 shows the correlation between OH$_{bg}$ and the product $k_{O_3}[VOC][O_3]$ of measured unsaturated VOC concentration (Table S1), [O$_3$] and the relevant ozonolysis rate coefficients. The data points belonging to the tree-cutting period are depicted in red, which naturally correspond to a larger OH$_{bg}$ concentration for similar concentrations of measured VOCs during the rest of the campaign, as the additional contribution from the non-identified BVOCs is neglected. The overall correlation appears to be pretty poor in particular due to the few points scattering in the lower right corner. These points all belong to three consecutive days, from 26 to 28 July, which were characterised by high temperature and large concentrations of BVOCs (Table S3). As noticeable in Fig. 4, during those 3 days the OH$_{bg}$ strongly deviates from the temperature trends and reaches lower values. At present, the reason for such a low concentration of OH$_{bg}$, during a period which should favour its formation if it originates from SCIs, is unclear. The instrument was left unattended at the site and the drop in the quality of the signals required its shutdown on the evening of 28 July. However, as no evidence was found to suggest an error in the data, the points have not been omitted. Excluding that period yields a correlation factor of $R = 0.65$. The correlation line intercept could arise for a number of reasons. Unmeasured components of the OH reactivity (i.e. unspeciated VOCs) are not accounted for in the calculation, and doing so would shift the data to higher [VOC], decreasing the positive intercept. This is also consistent with a higher intercept for the tree-cutting period, where a larger unexplained...
OH reactivity was observed. It is also conceivable that the intercept is in part due to an additional, non-ozonolysis source of background OH. One candidate for the night-time periods could be NO$_3$ as found in the work by Fuchs et al. (2016). Unfortunately, there was no measurement of the NO$_3$ radical during the HOPE 2012 campaign, but based on previous studies at the site (Handisides et al., 2003), a concentration up to 14 pptv of NO$_3$ could be present and could have a detectable impact.

Apart from the possible partial origin of OH$_{bg}$ from NO$_3$ or other interferences, there are also indications that the background OH could originate from ozonolysis of unsaturated biogenic compounds. The correlation analysis requires that all VOCs are accounted for, and omitting large contributions from unspeciated VOCs, as evidenced, for example, by OH reactivity measurements, can be expected to reduce the correlation as observed in the case of HUMPPA-COPEC 2010. The reason for the lack of correlation during the period from 26 to 28 July 2012 during HOPE-2012 characterised by large BVOC emissions remains unclear.

### 4.4 Correlation of OH$_{bg}$ with P(H$_2$SO$_4$)$_{unex}$

During both campaigns, measurements of H$_2$SO$_4$, SO$_2$, OH, and CS (condensation sink) were performed, allowing the calculation of the sulfuric acid budget in the gas phase. As shown by Mauldin III et al. (2012), during the HUMPPA-COPEC 2010 campaign the well-known SO$_2$ oxidation process by OH (Wayne, 2000) (Eq. 1) was not sufficient to explain the measured concentration of H$_2$SO$_4$. As shown in Sect. 3.1, half of the production rate of H$_2$SO$_4$, $\sim 1 \times 10^4$ molecules cm$^{-3}$ s$^{-1}$, cannot be explained by reaction with OH radicals (Fig. 8). The missing oxidant is assumed to be SCIs, as discussed in Sect. 3.1, because of their fast reaction rate with SO$_2$. As our hypothesis about the origin of the OH$_{bg}$ supports this assumption, we compared the [H$_2$SO$_4$]$_{unex}$ observed during the HUMPPA-COPEC 2010 campaign with the OH$_{bg}$ multiplied by SO$_2$ for the ground-based period when the instruments (HORUS and CIMS) measured side by side (Fig. 9). The two datasets indicate a correlation coefficient of $R = 0.6$, suggesting that whichever species is responsible for the oxidation of SO$_2$ is related to the formation of OH within the HORUS instrument.

Note that for the HOPE 2012 campaign the same budget calculation shows only a small fraction (10 %) of unexplained H$_2$SO$_4$ production rate (Fig. 1).

If we assuming SCIs to be the unknown SO$_2$ oxidant, the results observed in both campaigns are in agreement with the modelling study by Boy et al. (2013), who analysed mea-
measurements at the same sites described in this study. Similar to our result, they found a larger contribution of SCIs in the formation of H$_2$SO$_4$ for the boreal forest compared to rural Germany. As the OH concentration differs by, on average, less than 50% between the two environments, a similar concentration of SCIs in HOPE to that calculated for HUMPPA-COPEC 2010 would contribute up to 30% in the formation of H$_2$SO$_4$. However, the H$_2$SO$_4$ budget during this campaign can approximately be closed by only considering the measured OH concentrations, suggesting that the concentration of SCIs in this environment is smaller than that during the HUMPPA-COPEC 2010 campaign. This is consistent with the calculation in Sect. 3 based on the smaller reactivity and hence smaller VOC concentration in this environment.

4.5 Scavenging experiments

A series of scavenging tests of the OH$_{bg}$ was performed during the HOPE 2012 campaign to help identify the interfering species. SO$_2$ was chosen as a scavenger for the species causing the OH$_{bg}$, as it has been shown in several laboratory studies to react quickly with SCIs ($k \approx 3.3 \times 10^{-11}$ cm$^3$ molecule$^{-1}$ s$^{-1}$) mostly independently of their structure (Taatjes et al., 2014). The injection of SO$_2$ was performed through the IPI system (Novelli et al., 2014a) together with an OH scavenger. First the OH scavenger propane was injected within the IPI to remove the atmospheric OH; subsequently, SO$_2$ was injected in addition to the OH scavenger (Fig. 10). A set of experiments were performed at the end of the campaign, resulting in the depletion of the OH$_{bg}$ signal as shown in Fig. 10. The concentration of SO$_2$ is small enough not to scavenge SCIs inside the low-pressure section of the instrument, nor is it additionally removing atmospheric OH within the IPI system as the lifetime of OH by reaction with SO$_2$ is 200 times that of propane. With the addition of SO$_2$ (1 \times 10^{13}$ molecules cm$^{-3}$ in the sampled air) it is possible to suppress the OH$_{bg}$ signal from the instrument to within the zero noise, indicating that the OH$_{bg}$ signal originates from an SCI-like species that reacts with SO$_2$ and decomposes unimolecularly to OH. Similar results were obtained in later field campaigns; this will be discussed in the pertaining upcoming publications. Note that it is not possible to link the signal strength directly to an OH or precursor concentration, as analysed in the following section.

4.6 SCIs as a source of background OH

During the HUMPPA-COPEC 2010 campaign the background OH showed a strong exponential relationship with temperature ($R = 0.8$) and it correlates with unexplained OH reactivity ($R = 0.5$), which suggests correlation with BVOCs, ozone ($R = 0.7$), and also the P(H$_2$SO$_4$)$_{unex}$ ($R = 0.6$). During the HOPE 2012 campaign a weak exponential correlation with temperature was recognised ($R = 0.5$), but no correlation was observed with OH reactivity. The OH$_{bg}$ correlated with the product of ozone and unsaturated VOCs for most of the campaign ($R = 0.6$), although not for a period of 3 days at the end of July with partly higher BVOC–O$_3$ turnover. In addition, during HOPE 2012 the OH$_{bg}$ signal was scavenged by the addition of SO$_2$.

All evidence presented indicates that substantial parts of the OH$_{bg}$ originate from a species formed during the ozonolysis of unsaturated VOCs that decomposes into OH, is removable by SO$_2$ and, if present in a significant concentration, increases the H$_2$SO$_4$ production. We are currently not aware of any chemical species, other than SCIs, known to oxidise SO$_2$ at a fast enough rate and also decompose into OH. In addition, HORUS was shown to be sensitive to the OH formed after unimolecular decomposition of SCIs in the low-pressure region of the instrument (residence time 2 ms) in controlled laboratory studies (Novelli et al., 2014b). During the HUMPPA-COPEC 2010 campaign, the correlation with OH reactivity improved when considering only data during night time, the period during which a higher fraction of the production rate of OH could not be accounted for (Hens et al., 2014). Indeed, during the night recycling via HO$_2$+NO is low due to the negligible NO concentration; therefore, a different path of formation of OH is expected. One likely path could be the formation of OH from excited and stabilised CIs formed from ozonolysis of unsaturated compounds.

The considerations above are all consistent with the hypothesis that OH$_{bg}$ largely originates from unimolecular decomposition of SCIs in the field as well as in the laboratory. Attempts to analyse the absolute concentration of SCIs based on our OH$_{bg}$, however, indicate that this hypothesis is not without difficulties. A particular problem is that to date no method is available to produce and quantify a known concentration of a specific SCI conformer, which
precludes the absolute calibration of SCI-generated OH. A priori, it seems unlikely that the IPI-LIF-FAGE instrument calibration factor for ambient OH, i.e. sampled from outside the instrument through the nozzle, is identical to the sensitivity for OH generated inside. The transmission factor through our nozzle pinhole is currently not known for OH radicals; the calibration factor used for ambient OH accounts for this transmission as well as, for example, OH losses on the walls, alignment of the white cell, transmission optics, and response of the MCP. These last three factors should affect the OH generated from any interfering species similarly, while wall losses and transmission through the pinhole are different and possibly also differ between SCI conformers. Additionally, different SCIs vary in their unimolecular decomposition rates and hence affect calibration by a different time-specific OH yield. For example, theoretical studies (Vereecken and Francisco, 2012) and laboratory experiments (Smith et al., 2016) indicate that acetone oxide will decompose faster than syn-acetaldehyde oxide, causing the formation of a different amount of OH, which in turn will also be affected by different loss rates in the low-pressure segment of the instrument. Thus, it is not possible to convert the internal OH to an absolute SCI concentration since the mixture of SCIs is not known. At best one could obtain an “average” sensitivity factor, if one knew the OHbg formed from a series of reference SCI conformers, and if the ambient SCI speciation is known and not too strongly dependent on reaction conditions. To further illustrate the need of a SCI-specific calibration, we try to simply calculate the external [SCI] from the internal OHbg signal strength, calibrated based on the combined experimental and modelling study by Novelli et al. (2014b). For a SCI mixture that behaves identically to syn-CH3CHOO, the OHbg from the HUMPPA-COPEC 2010 campaign would then indicate an external [SCI] > 2 x 10^7 molecules cm^-3, well above the estimates presented in Sect. 3. Moreover, the observed OHbg signal interpreted in this way would imply an ambient OH production exceeding 4 x 10^8 molecules cm^-3 s^-1, clearly in disagreement with known chemistry, and also inconsistent with our estimates (Table 2). If we assume a faster decomposition rate for the SCIs of 200 s^-1, a higher fraction of the SCI decomposes in the low-pressure region, i.e. 80 % compared to 25 % for kuni = 20 s^-1. This leads to a higher OH signal per SCI, and from this a [SCI] of 4.0 x 10^8 molecules cm^-3, though the implied ambient OH production would remain significantly too high. Thus, the conversion of the OH signal to an absolute concentration of ambient SCIs is not unambiguous without full SCI speciation and knowledge of their chemical kinetics. Note, furthermore, that these [SCI] estimates would represent a lower limit as we only observe SCIs that decompose to OH, whereas, for example, anti-SCIs convert to acids/esters.

In an effort to work towards SCI-specific calibration, we probed the transmission of OH and syn-CH3CHOO through the nozzles and the low-pressure region in the instrument, with explorative laboratory tests using a traditional nozzle and a molecular beam skimmer nozzle, where the latter has much thinner sidewalls and a significantly narrower gas expansion, strongly reducing wall contact. The laboratory test showed that the OH radical has a 23 % higher transmission through the molecular beam nozzle compared to the traditional nozzle. The syn-acetaldehyde oxide did not show any statistical difference in the transmission between the two nozzles. This indicates that (a) SCIs and OH have a different transmission efficiency and most likely different wall losses, underlining that the OH calibration factor is not applicable to SCIs for ambient measurements, and (b) that the calibration factor for OH obtained for ambient OH alone does not allow the quantification of the absolute OH concentration in the low-pressure section of the FAGE instrument. This is the fundamental reason why the earlier simple estimate of [SCI] and OH production leads to strong overestimations.

In addition to the above effects, one should also consider that OH production from SCIs in the low-pressure section might be catalysed to proceed at rates beyond their ambient counterpart, biasing our interpretation of their ambient fate. The catalysis might involve wall-induced isomerisation of the higher-energy anti-SCIs to the more stable, OH-producing syn-SCIs, which would artificially increase the syn:anti ratio. Another possibility is the evaporation of clusters stabilising the SCIs, as it is known that SCIs efficiently form complexes with many compounds, including water, acids, alcohols, hydroperoxides, HOx radicals, etc. (Vereecken and Francisco, 2012). Redissociation of secondary ozonides (SOZs) seems less important, except perhaps the SOZs formed with CO2 (Aplincourt and Ruiz-López, 2000), which has no alternative accessible unimolecular channels. At present, insufficient (if any) information is available to assess the impact of such catalysis.

Taking into account the factors considered above, and assuming that the estimates for the SCI concentration in both environments are correct, it appears unlikely that SCIs are responsible for such a large OHbg signal as observed by the HORUS instrument. If SCIs were to be solely responsible for the OHbg signal, the HORUS instrument would need to be far more sensitive to the detection of SCIs than to the detection of OH radicals by, for example, pinhole losses that are 100 times smaller for SCIs than for OH radicals. The evident discrepancy between the qualitative evidence in support of the SCI hypothesis and the current quantitative difficulty in reconciling the OHbg signal with the estimated ambient concentration of SCIs does not allow an unequivocal identification of the origin of the OHbg within our system. It cannot be excluded that multiple species are contributing to the OHbg signal. NO3 chemistry during night time has been identified as a possible source of OHbg in the LIF-FAGE instrument of the FZ-Jülich (Fuchs et al., 2016). However, in the case of the large observed night-time OHbg concentrations during HUMPPA-COPEC 2010, the measured night-time NO3 concentrations...
concentrations were below 1 ppt and therefore too small to explain the observed OHbg.

5 Conclusions

We estimated a steady-state concentration of SCIs for the HUMPPA-COPEC 2010 and the HOPE 2012 campaigns based on a large dataset. Starting from four different approaches, i.e. based on unaccounted (i.e. non-OH) H2SO4 oxidant, measured VOC concentrations, unexplained OH reactivity, or unexplained production rates of OH, we estimated the concentration of SCIs to be between $\sim 10^3$ and $\sim 10^9$ molecules cm$^{-3}$. The highest values in this range are linked to an assumed low rate coefficient for SCI + SO2 of $5.0 \times 10^{-13}$ cm$^3$ molecule$^{-1}$ s$^{-1}$ (see Sect. 3.1), which is at odds with a larger body of more direct measurements on this rate coefficient. Hence, higher SCI values appear to be relatively less likely. We thus obtain an average SCI concentration of about $5.0 \times 10^4$ molecules cm$^{-3}$, with an order of magnitude uncertainty, for both campaigns. At such concentrations, SCIs are expected to have a significant impact on H2SO4 chemistry during the HUMPPA-COPEC 2010 campaign, while during the HOPE 2012 campaign their impact is much smaller and possibly negligible.

The predicted SCI concentrations derived in this study are low, likely not exceeding $10^5$ molecules cm$^{-3}$; therefore, the presence of SCIs is unlikely to have a large impact on atmospheric chemistry; the main exception appears to be H2SO4 production in selected environments.
