Spin singlet pairing in the superconducting state of NaxCoO2 1.3H2O: evidence from a 59Co Knight shift in a single crystal

Abstract
We report a 59Co Knight-shift measurement in a single crystal of the cobalt oxide superconductor NaxCoO2·1.3H2O (Tc=4.25 K). We find that the shift due to the spin susceptibility, Ks, is substantially large and anisotropic, with the spin shift along the a-axis Kas being two times that along the c-axis Kcs. The shift decreases with decreasing temperature (T) down to T≈100 K, then becomes a constant until superconductivity sets in. Both Kas and Kcs decrease below Tc. Our results indicate unambiguously that the electron pairing in the superconducting state is in the spin singlet form.

We report a $^{59}$Co Knight-shift measurement in a single crystal of the cobalt oxide superconductor Na$_4$CoO$_2$·1.3H$_2$O ($T_c=4.25$ K). We find that the shift due to the spin susceptibility, $\chi_s$, is substantially large and anisotropic, with the shift along the $a$-axis $\delta K_s^a$ being two times that along the $c$-axis $\delta K_s^c$. The shift decreases with decreasing temperature ($T$) down to $T=100$ K, then becomes a constant until superconductivity sets in. Both $\delta K_s^a$ and $\delta K_s^c$ decrease below $T_c$. Our results indicate unambiguously that the electron pairing in the superconducting state is in the spin singlet form.

DOI: 10.1103/PhysRevB.73.180503

The recently discovered superconductivity in cobalt oxide Na$_4$CoO$_2$·1.3H$_2$O has attracted considerable attention. The new material consists of two-dimensional CoO$_2$ layers that bear a similarity to high-temperature (high-$T_c$) copper oxide superconductors. A simple but widespread view of the electronic state is that increasing the sodium content $x$ adds $x$ electrons to the spin 1/2 network in the CoO$_2$ layer, which is similar to the case of doping the spin 1/2 network in the CuO$_2$ layer of the high-$T_c$ cuprates. However, there is a large difference between these two classes of transition-metal oxides. Namely, Co forms a triangular lattice in the cobaltate, instead of a square lattice in the cuprates. Because of this crystal structure, exotic superconducting states are expected in the cobaltate. So far, chiral $d$-, $p$-, $f$-, and $i$-wave states have been proposed theoretically. The $d$- and $i$-wave states are spin singlet states, while the remainder are spin triplet states.

Indeed, the nuclear spin-lattice relaxation rate ($1/T_1$) measurements by the authors indicate that the superconducting state is unconventional: $1/T_1$ is proportional to $T^0$ below the transition temperature $T_c$, suggesting line nodes in the gap function. However, the symmetry of the spin pairing has been unclear. Previous measurements of the angle-averaged Knight shift in powder samples have resulted in controversial conclusions.

Kato et al. reported no change of the shift below $T_c$, while Kobayashi et al. found a decrease of the shift in a powder sample. The former suggested triplet pairing, while the latter concluded to $s$-wave pairing. The difficulty in growing the samples, which often accompany a secondary phase that gives rise to a spurious NMR peak overlapping the main peak in question, complicates the data analysis in powder samples. Therefore, measurements of the spin susceptibility via the Knight shift in single crystals are required.

In particular, the Knight shift in the $c$-axis direction is essential to distinguish various pairing states proposed theoretically. This is because even for triplet pairing, the spin susceptibility in the $a$-axis direction can be reduced below $T_c$ but that along the $c$-axis direction should remain unchanged across $T_c$. Kobayashi et al. have attempted to align small single crystal platelets, but their samples contain multiple phases with an almost equal amount of nonsuperconducting composition, which contaminated the NMR signal observed. So far, no work has been reported to determine the absolute value of the $c$-axis shift due to the spin susceptibility, which is important in discussing the superconducting state properties.

In this paper, we report the first complete data set of the $^{59}$Co Knight shift in a high quality single crystal with $T_c=4.25$ K. We find that the spin contribution to the Knight shift is significantly large and anisotropic. The spin Knight shift along both the $a$- and the $c$-axis decreases below $T_c$. Our results indicate unambiguously that the spins that form the Cooper pairs in the superconducting state are antiparallel.

The single crystal of Na$_{4.43}$CoO$_2$·1.3H$_2$O used in this study was grown by the traveling solvent floating zone (TSFZ) method, as described in a previous publication. AC susceptibility measurement using the in situ NMR coil indicates that the $T_c$ at the zero magnetic field is 4.25 K (data not shown). NMR experiments were performed using a home-built phase-coherent spectrometer. The NMR spectra were taken by changing the external magnetic field ($H$) at a fixed rf and recording the echo intensity step by step.

Figure 1 shows a typical example of the NMR spectra for $H\parallel c$ axis and $H\parallel a$ axis. As can be seen in Fig. 1(a), a sharp central transition line accompanied by six satellites due to the nuclear quadrupole interaction are observed. There is essentially no signal intensity between the sharp peaks, which indicates good quality of the single crystal.

Figure 2 shows the temperature dependence of the Knight-shift $K_s$ with the field applied along the $a$ axis, and $K_c$ with the field applied along the $c$ axis, $K_s$ was determined from the central peak as well as from the midpoint between the two first satellites; results obtained by the two procedures agree well. $K_c$ was determined from the central transition, by taking into account the shift due to the quadrupolar interaction effect. Upon decreasing the temperature from 260 K, both $K_s$ and $K_c$ decrease, but tend to be saturated below $T=100$ K before superconductivity sets in. The decrease of the Knight shift with decreasing temperature is consistent with the bulk susceptibility results reported by
FIG. 1. (Color online) $^{59}$Co NMR spectra in Na$_{0.44}$CoO$_2$·1.3H$_2$O at $T=4.2$ K with $H\parallel c$ axis at 14.1 MHz (upper panel) and with $H\parallel a$ axis at 59.4 MHz (lower panel).

Foo et al. and for the sample used in the present study, although a previous measurement has failed to detect the temperature dependence. Below, we show that the spin shift is quite large and can be used to distinguish the pairing symmetry in the superconducting state.

The Knight shift is composed of the spin part $K'$ due to the spin susceptibility ($\chi'$) and the orbital part $K'^{\text{orb}}$ due to the orbital susceptibility ($\chi^{\text{orb}}$), which is $T$ independent.

$$K = K'^{\text{orb}} + K'$$

(1)

$$K' = A^{bf} \chi'$$

(2)

where $A^{bf}$ is the hyperfine coupling constant between the nuclear and the electron spins. Figure 3 shows the plot of $K_a$ vs $K_c$. The straight line is a fit to the data, which gives $K_a = 0.5K_c + \text{const}$ which means that $K_a' = 2K_c'$. The temperature dependence of the Knight shift is similar to the case of the electron-doped cuprate superconductor (Pr$_{0.95}$La$_{0.05}$)$_2$CeCuO$_4$, in which $K_a$ also decreases with decreasing temperature and becomes a constant below $T = 60$ K.

Let us focus on the temperature dependence of the Knight shift below $T_c$. First, both $K_a$ and $K_c$ decrease below $T_c(H)$, as can be seen in Fig. 4, which shows the enlarged part of the shift below $T=5$ K for $H(3.82\, \text{T})\parallel a$ axis and $H(0.93\, \text{T})\parallel c$ axis. $T_a(H\parallel a)$ and $T_c(H\parallel c)$ at which the shift decreases is 3.5 and 3.1 K, respectively, which is in good agreement with the report by Chou et al. Figure 5 compares two of the spectra above and below $T_c$, respectively, for both field configurations. The reduction of $K_a$ and $K_c$, at $T=1.6$ K amounts to 0.2% and 0.13%, respectively. The smaller reduction of $K_c$ is mostly due to the smaller spin part $K_c'$. For $H\parallel c$ axis, we have also carried out measurements at 14.1 MHz ($H \sim 1.38$ T), and found a detectable shift change between

FIG. 3. (Color online) The plot of $K_a$ vs $K_c$. The straight line is the best fit to the data, which gives $K_a' = 2K_c'$. The arrows indicate the estimated orbital contributions to the shifts (see text).

FIG. 4. (Color online) The enlarged part of the $^{59}$Co Knight shift at low temperatures. The vertical arrows indicate $T_a(H)$ at the respective external fields. The horizontal arrows indicated $K_a^{\text{orb}}$, the shift due to orbital susceptibility (see text for the estimation).
found that the spin order in Na$_8$CoO$_2$ is antiferromagnetic, with alternative rows of Co$^{4+}$ ($s=1/2$) and Co$^{3+}$ ($s=0$) in the CoO$_2$ plane. In other words, the triangles with regard to the spin configuration are effectively squared. In fact, both the Knight shift found in this study and the temperature dependence of $1/T_1T$ in the normal state in Na$_8$CoO$_2$·1.3H$_2$O ($x =0.25$−$0.35$) (Ref. 12) point to the presence of antiferromagnetic correlations, which would favor $d$-wave pairing.

Next, we attempt to separate the $K'$ and $K_{orb}$ from the observed shift data, and argue that the data below $T_c$ can be consistently accounted for by an anisotropic superconducting state with nodes in the gap function and with spin singlet pairing. In $s$-wave superconductors with an isotropic gap, the spin susceptibility outside the vortex cores vanishes completely at a temperature far below $T_c$. In anisotropic superconductors with nodes in the gap function, however, the spin susceptibility outside the vortex cores can remain a finite value, since the quasiparticle state can be extended from the vortex core along the nodal directions. Volovik pointed out that the density of such a delocalized quasiparticle state, $N_0$, is proportional to $\sqrt{H/H_c}$ where $H_c$ is the upper critical field. Indeed, in an overdoped cuprate superconductor, it has been found that $N_0/N_0\sim 0.7\sqrt{H/H_c}$ (Ref. 29), where $N_0$ is the density of states (DOS) in the normal state. Note that the coefficient 0.7 is less than 1, because NMR only probes the DOS outside the vortex cores. If we use the data of $H_{c2}^s(0)=8$ T and $H_{c2}^s(0)=4$ T by Chou et al. and the same $N_0$ as in the cuprate, we obtain $K_{orb} = 2.94\%$ from the relation $0.7\sqrt{H/H_c}K_c(4.2 K) - K_{orb} = K_c(1.6 K) - K_{orb}$. Once $K_{orb}$ is known, one readily obtains $K_c = 2.02\%$ from the $K_c$ vs $H$ plot in Fig. 3. Such an estimate consistently explains the $K_c$ result: the $H$-induced shift at the lowest temperature due to $N_0(H\parallel c)$ is calculated to be 0.05%, which is in fair agreement with the experimental result of 0.04±0.03%. Note that $K_{orb} = 0.72\%$, which is about twice the spin shift in cuprate superconductors. Finally, we comment that the estimated $K_{orb}$ agrees fairly well with that independently estimated from the Knight shift vs DC susceptibility plot.

In conclusion, the $^{59}$Co NMR measurements in a single crystal of Na$_8$CoO$_2$·1.3H$_2$O ($T_{c}=4.25$ K) allowed us, for the first time, to obtain a complete data set of the Knight shift. We found that the shift due to the spin susceptibility is substantially large (0.72% along the a axis) and anisotropic with $K'_{a}=2K'_{c}$. Both $K'_a$ and $K'_c$ decrease below $T_c$, indicating that the spin pairing of the Cooper pairs is in the singlet state. Our work that settled the electron pairing symmetry in the superconductor state should help pave the first step toward understanding the mechanism of the superconductivity in this new class of materials.

We thank M. Nishiyama for assistance with some of the measurements. This work was partially supported by MEXT grants for scientific research.
18. The nuclear quadrupole resonance frequency, $v_Q$, is temperature independent below $T = 90$ K.
25. From the central peak that consists almost equally of the contribution from superconducting and nonsuperconducting compositions, Kobayashi et al. have reported a shift change of 0.04 ± 0.01% between $T = 3$ K and 1.5 K (Ref. 16), which is less than one quarter (1/4) the value we found. Note that such shift change of 0.04±0.01% is comparable to the estimated $K^\text{dia}$. In fact, very recently Ihara et al. [J. Phys. Soc. Jpn. 75, 013708 (2006)] claimed that $K'$ does not decrease beyond such $K^\text{dia}$.
