Abstract. We have developed an improved version of the National Institute for Environmental Studies (NIES) three-dimensional chemical transport model (TM) designed for accurate tracer transport simulations in the stratosphere, using a hybrid sigma-isentropic (σ-θ) vertical coordinate that employs both terrain-following and isentropic parts switched smoothly around the tropopause. The air-ascending rate was derived from the effective heating rate and was used to simulate vertical motion in the isentropic part of the grid (above level 350 K), which was adjusted to fit to the observed age of the air in the stratosphere. Multi-annual simulations were conducted using the NIES TM to evaluate vertical profiles and dry-air column-averaged mole fractions of CO$_2$ and CH$_4$. Comparisons with balloon-borne observations over Sanriku (Japan) in 2000–2007 revealed that the tracer transport simulations in the upper troposphere and lower stratosphere are performed with accuracies of ~5% for CH$_4$ and SF$_6$, and ~1% for CO$_2$ compared with the observed volume-mixing ratios. The simulated column-averaged dry air mole fractions of atmospheric carbon dioxide (XCO$_2$) and methane (XCH$_4$) were evaluated against daily ground-based high-resolution Fourier Transform Spectrometer (FTS) observations measured at twelve sites of the Total Carbon Column Observing Network (TCCON) (Bialystok, Bremen, Darwin, Garmisch, Izaña, Lamont, Lauder, Orléans, Park Falls, Sodankylä, Tsukuba, and Wollongong) between January 2009 and January 2011. The comparison shows the model’s ability to reproduce the site-dependent seasonal cycles as observed by TCCON, with correlation coefficients typically on the order 0.8–0.9 and 0.4–0.8 for XCO$_2$ and XCH$_4$, respectively, and mean model biases of ±0.2% and ±0.5%, excluding Sodankylä, where strong biases are found. The ability of the model to capture the tracer total column mole fractions is strongly dependent on the model’s ability to reproduce seasonal variations in tracer concentrations in the planetary boundary layer (PBL). We found a marked difference in the model’s ability to reproduce near-surface concentrations at sites located some distance from multiple emission sources and where high emissions play a notable role in the tracer’s budget. Comparisons with aircraft observations over Surgut (West Siberia), in an area with high emissions of methane from wetlands, show contrasting model performance in the PBL and in the free troposphere. Thus, the PBL is another critical region for simulating the tracer total column mole fractions.

1 Introduction

Carbon dioxide ($\text{CO}_2$) and methane ($\text{CH}_4$) are the greenhouse gases that contribute the most to global warming (IPCC, 2007). Recent studies of global sources and sinks of greenhouse gases, and their concentrations and distributions, have been based mainly on in situ surface measurements (GLOBALVIEW-CH4, 2009; GLOBALVIEW-CO2, 2010). The diurnal and seasonal “rectifier effect”, the covariance between surface fluxes and the strength of vertical mixing, and the proximity of local sources and sinks to surface measurement sites all have an influence on the measured and simulated concentrations, and complicate the interpretation of results (Denning et al., 1996; Gurney et al., 2004; Baker et al., 2006).

In contrast, the vertical integration of mixing ratio divided by surface pressure, denoted as the column-averaged dry-air mole fraction (DMF; denoted $X_G$ for gas $G$) is much less sensitive to the vertical redistribution of the tracer within the atmospheric column (e.g. due to variations in planetary boundary layer (PBL) height) and is more directly related to the underpinning surface fluxes than are near-surface concentrations (Yang et al., 2007). Thus, column-averaged measurements and simulations are expected to be very useful for improving our understanding of the carbon cycle (Yang et al., 2007; Keppel-Aleks et al., 2011; Wunch et al., 2011).

The Short-Wave InfraRed (SWIR) measurements from the SCIAMACHY imaging spectrometer onboard the ENVISAT satellite (Bovensmann et al., 1999) and the Japanese Greenhouse gases Observing SATellite (GOSAT) (Yokota et al., 2009) show some usefulness in determining the dry-air column-averaged mole fractions of carbon dioxide ($\text{XCO}_2$) and methane ($\text{XCH}_4$) (Bergamaschi et al., 2007, 2009; Bloom et al., 2010). However, the GOSAT retrieval algorithms are under continuing development and require reliable data for evaluation. One appropriate way to validate GOSAT is to use ground-based high-resolution Fourier Transform Spectrometer (FTS) observations from the Total Carbon Column Observing Network (TCCON) (Butz et al., 2011; Morino et al., 2011; Parker et al., 2011; Wunch et al., 2011). Ground-based FTS observations of the absorption of direct sunlight by atmospheric gases in the near-infrared (NIR) spectral region provide accurate measurements of the total columns of greenhouse gases (Wunch et al., 2010). Due to the limited number of TCCON sites, there is a relatively uneven spatial distribution of measurements, and measurements are not continuous because they depend on the cloud conditions (Wunch et al., 2011, Crisp et al., 2012). As a result, there are notable temporal and spatial gaps in the data coverage, particularly at high latitudes and over heavily clouded areas such as South America, Africa, and Asia; in such areas, model data can be used (Parker et al., 2011).

The synoptic and seasonal variabilities in $\text{XCO}_2$ and $\text{XCH}_4$ are driven mainly by changes in surface pressure, the tropospheric volume-mixing ratio (VMR) and the stratospheric concentration, which is affected in turn by changes in tropopause height. The effects of variations in tropopause height are more pronounced with increasing contrast between stratospheric and tropospheric concentrations; i.e., the influence is greater for $\text{CH}_4$ than for $\text{CO}_2$ due to $\text{CH}_4$ oxidation by OH, O(1D), and Cl in the stratosphere. A 30-ppbv change in tropospheric $\text{CH}_4$ or a 30-hPa change in tropopause height would produce a $\sim$1.5% variation in sea level $\text{XCH}_4$ (Washenfelder et al., 2003).

A precision of 2.5 ppm (better than 1%) for $\text{CO}_2$ (Rayner and O’Brien, 2001) and 1%–2% for $\text{CH}_4$ (Meirink et al., 2006) for monthly mean column-integrated concentrations on a regional scale is needed to reduce uncertainties in predictions of the carbon cycle. The target requirement formulated for the candidate Earth Explorer mission A-SCOPE mission is 0.02 Pg C yr$^{-1}$ per 106 km$^2$ or 0.1 ppm (Ingmann, 2009; Houweling et al., 2010). Transport-model-induced flux uncertainties that exceed the target requirement could also limit the overall performance of $\text{CO}_2$ missions such as GOSAT. However, the model accuracy requirement may depend on the measurement sensitivity (averaging kernel) for different tracers. If the measurement has little or no sensitivity to the tracer VMR in a given altitude region, then the accuracy of the model tracer concentrations in that region is irrelevant. A key element in accurately determining $\text{XCO}_2$ and $\text{XCH}_4$ is to obtain precise simulations of tracers throughout the atmosphere, including the stratosphere as well as the PBL.

Hall et al. (1999) suggested that many chemical transport models (CTMs) demonstrate some common failings of model transport in the stratosphere. The difficulty of accurately representing dynamical processes in the upper troposphere (UT) and lower stratosphere (LS) has been highlighted in recent studies (Mahowald et al., 2002; Waugh and Hall, 2002; Monge-Sanz et al., 2007). While there are many contributing factors, the principal factors affecting model performance in vertical transport are meteorological data and the vertical grid layout (Monge-Sanz et al., 2007).

The use of different meteorological fields in driving chemical transport models can lead to diverging distributions of chemical species in the upper troposphere/lower stratosphere (UTLS) region (Douglass et al., 1999). Several studies based on multi-year CTM simulations have shown that vertical winds directly supplied from analyses can result in an over-prediction of the strength of the stratospheric circulation and an under-prediction of the age of air (Chipperfield, 2006; Monge-Sanz et al., 2007). On the isentropic grid, the diabatic heating rate can be substituted for the analysed vertical velocity. A radiation scheme or recalculated radiation data can be used to resolve some of the problems of vertical winds from assimilated data products. Weaver et al. (1993) found that the use of a radiative scheme for long-term simulations gave a better representation of the meridional circulation, compared with simulations using the analysed vertical winds.
The isentropic vertical coordinate system has notable advantages over other types of coordinate systems, such as height, pressure, and “sigma” (Arakawa and Moorthi, 1988; Hsu, 1990), due to its ability to minimize vertical truncation and the non-existence of vertical motion under adiabatic conditions, except for diabatic heating (Bleck, 1978; Kalnay, 2002). These advantages result in reduced finite difference errors in sloping frontal surfaces, where pressure or z-coordinates tend to have large errors associated with poorly resolved vertical motion. The implementation of an isentropic coordinate with a radiation scheme helps to avoid erroneous vertical dispersion and enables the accurate calculation of vertical transport in the UTLS region (Mahowald et al., 2002; Chipperfield, 2006).

The aim of this study is to develop a NIES TM version with an improved tracer transport simulation in the stratosphere by implementing a sigma-isentropic coordinate system with an air-ascending rate derived from the effective heating rate, in order to obtain a more accurate simulation of atmospheric CO$_2$ and CH$_4$ profiles, and corresponding column-averaged concentration. The remainder of the paper is organized as follows. The model modifications are described in Sect. 2, and Sect. 3 presents an evaluation of these modifications with comparison against balloon-borne in situ observations in the stratosphere. Also examined is the model’s performance in reproducing the near-surface concentration and free-troposphere vertical profiles of CH$_4$, XCO$_2$ and XCH$_4$ simulated by NIES TM in comparison against FTS observations at twelve TCCON sites between January 2009 and January 2011. Finally, a discussion (Sect. 4) and conclusions (Sect. 5) are provided.

2 Model description

This section describes the formulation of the NIES model version (denoted NIES-08.1i) used in this paper. Belikov et al. (2011) described the main model features, such as the flux-form dynamical core with a third-order van Leer advection scheme, a reduced latitude–longitude grid, a horizontal flux-correction method (necessary for mass conservation) and turbulence parameterization. However, the present paper focuses on the recently incorporated hybrid sigma-isentropic vertical coordinate and a change in the meteorological dataset used to drive the model.

2.1 Sigma-isentropic vertical coordinate

Previous NIES transport model versions with sigma-pressure and hybrid sigma-pressure vertical coordinate systems do not fully accommodate chemical and dynamical processes in the stratosphere, which results in the model failing to reproduce vertical tracer profiles. To overcome this issue, one can use climatological values of CO$_2$ and CH$_4$ in the stratosphere (Eguchi et al., 2010). However, this approach does not account for year-to-year VMR variation and can distort the meridional mass circulation in long-term simulations.

It was previously thought that because potential temperature under adiabatic motion is individually conserved, it could be used as an ideal vertical coordinate. However, in several studies that have been published since the first successful integration of hydrostatic equations in isentropic coordinates performed by Eliassen and Raustein (1968), a number of disadvantages have been revealed. Many of them relate to the fact that isentropes intersect the Earth’s surface. The combined hybrid vertical coordinate system consisted of the $\theta$ coordinate in the free atmosphere (where the air motion is quasi-adiabatic) with a $\sigma$ terrain-following system near the surface, which helps to avoid problems with the $\theta$ vertical coordinate (Bleck, 1978).

Hence, we follow the general methodology of Hsu and Arakawa (1990) and Konor and Arakawa (1997), and use the $\sigma$-$\theta$ hybrid sigma-isentropic coordinate that is isentropic in the UTLS region but terrain-following in the free troposphere. The coordinates switch smoothly near the tropopause level, as follows:

$$\sigma = \left\{ \begin{array}{ll} \frac{P + \Delta P}{(\Delta \theta/\theta)} \frac{1}{T} & \text{if } \theta \geq \theta_T, \\ 1 - \frac{(P_\theta - P_s)(1 - \sigma)}{(P_\theta - P_0)} & \text{if } \theta < \theta_T, \end{array} \right. \tag{1}$$

where $\zeta$ denotes the level of the sigma-isentropic grid as described in Table 1, $P_s$ and $P_\theta$ are atmospheric pressure and surface atmospheric pressure respectively, $\theta = T (P_s / P)^{(R/c_p)}$ is potential temperature, $T$ depicts temperature, $R$ is the molar gas constant, $c_p$ is the specific heat for a constant pressure, $\sigma_0$ and $P_0$ are “sigma” and pressure at the level $\theta_T$, respectively. We set $\theta_T = 360 \text{ K}$ to ensure that isentropes do not intersect the Earth’s surface.

2.2 Simulation of upward motion in the stratosphere

To calculate vertical transport in the $\theta$-coordinate domain of the hybrid sigma-isentropic coordinate, we use precalculated heating rates. Unlike the SLIMCAT model, which has an embedded diagnostic radiation scheme to calculate heating rates (Chipperfield, 2006), the NIES model interpolates the climatological heating rate at every meteorology data update step (3 h) at every model cell of the sigma-isentropic grid using a 2-D monthly distribution of the atmospheric reanalysis heating rate (see Sect. 2.3).

The most problematic region in modelling vertical transport is a level around the tropopause transition region known as the Tropical Tropopause Layer (TTL). Radiative heating in the TTL is a result of heating from the absorption of infrared radiation by ozone and carbon dioxide, balanced by infrared cooling, mainly from water vapor (Thuburn and Craig, 2002). The level termed as the “stagnation surface” (Sherwood and Dessler, 2003) occurs where the total heating rate $Q_{\text{total}} = 0$, and is demarcated by net cooling below and net
heating above. The height of this transition level is almost constantly around $\theta = 360$ K ($\approx 15$ km, 125 hPa) (Gettelman et al., 2004; Folkins et al., 1999). There is some variability in the level of $Q_{\text{total}} = 0$; e.g., $\pm 500$ m between different locations and seasons; $\pm 400$ m for individual profiles (Gettelman et al., 2004).

Among other aspects of Troposphere-to-Stratosphere Transport (TST) that are not adequately addressed, it is unclear how air parcels overcome the vertical gap between the main convective outflow around 350 K and the level with significant heating rates (Konopka et al., 2007). In some models, erroneous spurious meteorology, a diffusive numerical scheme (Eluszkiewicz et al., 2000), or extra vertical motion due to the implementation of vertical transport misrepresenting the adiabatic conditions are responsible for extra artificial mixing in this region, thereby obscuring the vertical transport problem.

In isentropic coordinates, the impact of such erroneous effects is significantly reduced. As a result, the use of a simulated heating rate leads to insufficient TST of tracers through the TTL. When models are unable to resolve a process explicitly, it is necessary to implement a parameterization to improve the simulation. Thus, Konopka et al. (2007) showed that more realistic tracer distributions are obtained by implementing the mixing parameterisation into a Chemical Lagrangian Model of the Stratosphere (CLaMS) with an isentropic vertical coordinate. Induced vertical mixing, driven mainly by vertical shear in the tropical flanks of subtropical jets, has been cited in explaining the upward transport of trace species from the main convective outflow to the tropical tropopause around 380 K (Konopka et al., 2007).

The total diabatic heating rates of different reanalysis products can produce dissimilar results (Fueglistaler et al., 2009). In our work, we implemented a scheme with additional transport in the TTL by increasing the air-ascending rate in the TTL, which was adjusted to fit the observed age of air in the stratosphere, as follows:

- For levels above 360 K (isentropic part of the vertical coordinate), the air-ascending rate was multiplied by 2.5.

## 2.3 Meteorological data and vertical resolution

NIES TM is an off-line model driven by Japanese reanalysis data covering more than 30 years from 1 January 1979 (Onogi et al., 2007). The period of 1979–2004 is covered by the Japanese 25-year Reanalysis (JRA-25), which is a product of the Japan Meteorological Agency (JMA) and the Central Research Institute of Electric Power Industry (CRIEPI). After 2005, a real-time operational analysis, employing the same assimilation system as JRA-25, has been continued as the JMA Climate Data Assimilation System (JCDAS). The JRA-25/JCDAS dataset is distributed on Gaussian horizontal grid T106 (320 × 160) with 40 hybrid $\sigma$-p levels. The 6-hourly time step of JRA-25/JCDAS is coarser than the 3-hourly data from the National Centers for Environmental Prediction (NCEP) Global Forecast System (GFS) and Global Point Value (GPV) datasets, which were used in the previous model version (Belikov et al., 2011). However, with a better vertical resolution (40 levels on a hybrid $\sigma$-p grid versus 25 and 21 pressure levels for GFS and GPV, respectively) it is possible to implement a vertical grid with 32 levels (versus 25 levels used before), resulting in a more detailed resolution of the boundary layer and UTLS region (Table 1).

The 2-D monthly distribution of the climatological heating rate used to calculate vertical transport in the $\theta$-coordinate domain of the hybrid sigma-isentropic coordinate is prepared from JRA-25 reanalysis data, which are provided as the sum of short- and long-wave components on pressure levels.

## 2.4 Turbulent diffusion and deep convection parameterization

The calculation of turbulent diffusion is similar to that described by Maksyutov et al. (2008). To separate the transport processes in the well-mixed near-surface layer and free troposphere, we used 3-hourly PBL height data taken from European Centre for Medium-Range Weather Forecasts...
The CO$_2$ simulation was started on 1 January 2000 with the initial distribution derived from GLOBALVIEW-CO$_2$ (2010) observations using prescribed fluxes from the Comprehensive Observation Network for Trace gases by AlrLiner (CONTRAIL) Transport Model Intercomparison (TMI) (Niwa et al., 2011), as follows:

1. Fossil fuel emissions are derived from the EDGAR-1998 distribution (Olivier and Berdowski, 2001) and the emission totals are scaled using the growth rate of the top 20 country-specific fossil fuel consumptions, as obtained from the Carbon Dioxide Information Analysis Center (CDIAC) (Boden et al., 2009).

2. The climatological inversion flux represents all non-fossil source/sink distributions over land and ocean, derived by inverse modelling with 12 TransCom3 models (Gurney et al., 2004) and from observational data obtained from GLOBALVIEW-CO$_2$ at 87 sites during 1999–2001 (Miyazaki et al., 2008).

3 Results

The current model version has been used in several tracer transport studies and was evaluated through participation in transport model intercomparisons (Niwa et al., 2011; Patra et al., 2011). The model results of tracer transport simulations show good consistency with observations and other models in the near-surface layer and in the free troposphere. However, the model performance in the UTLS region has not been evaluated in detail.

3.1 Validation of the mean age of air in the stratosphere

The mean age of air is purely a transport diagnostic. Modelers are ultimately interested in accurately simulating the distribution of trace gases that are affected by both transport and photochemistry (Waugh and Hall, 2002). The accurate determination of the chemical constituents that are transported across the tropopause, which are strongly affected by synoptic-scale events and other small-scale mixing processes, is a major challenge for modern CTMs (Hall et al., 1999). In the stratosphere, the vertical transport of substances is very weak due to the almost adiabatic conditions. However, many models are unable to reproduce sufficiently weak transport, especially in the tropical lower stratosphere, because the model grid does not reflect the underlying constraint that the flow is almost isentropic, making the model transport vulnerable to numerical errors (Mahowald et al., 2002). Generally, models tend to have ages of air in the stratosphere that are too young and tend to propagate the signal upward from the troposphere into the lower stratosphere too quickly, especially in the tropics (Hall et al., 1999; Park et al., 1999). By implementing a hybrid sigma-isentropic vertical coordinate, the observed age of air is more accurately
The age of the air increased monotonically with height through-the subtropics, and values of around 4–5 years at high latitudes. Both the model and observation estimations of the mean age indicate values have been increasing approximately linearly (Conway et al., 1994; Maiss et al., 1996). In spite of uncertainties due to non-linearity in tropospheric growth rates and the neglect of photochemical processes (Waugh and Hall, 2002), estimates performed with CO$_2$, SF$_6$, and other tracers show rather good agreement.

In this paper, SF$_6$ is simulated to derive the mean age of the air in the upper troposphere and in the lower stratosphere. The model was run for 22 years before the simulation results were analysed, because the age of stratospheric air was unchanged for the last 30 years (Engel et al., 2009).

Figure 1 shows the annual mean of the zonal-mean age of air obtained with NIES TM at an altitude of 20 km, together with the mean age values derived from CO$_2$ and SF$_6$ ER-2 aircraft observations (Andrews et al., 2001). Both the model and observation estimations of the mean age indicate values of approximately 1 year near the equator, large gradients in the subtropics, and values of around 4–5 years at high latitudes.

The vertical profiles of mean age derived from in situ measurements of CO$_2$ and SF$_6$ show that at all latitudes, the mean age of the air increased monotonically with height through-the stratosphere, with only weak vertical gradients above 25 km (Fig. 2). The model slightly overestimated the age of air in the tropics (Fig. 2a) and underestimated it at middle and high latitudes (Fig. 2b, c). The spikes in high-latitude profiles (Fig. 2c) are due to the sampling of fragments of polar vortex air. Despite this, the general shape of the isopleths in Fig. 3 is realistic and illustrates the balance of the meridional mass (Brewer–Dobson) circulation, which tends to increase latitu-

![Fig. 1. Mean age of air at 20 km altitude from NIES TM simulations (blue line), compared with the mean age of air derived from in situ ER-2 aircraft observations of CO$_2$ (Andrews et al., 2001) and SF$_6$ (Ray et al., 1999) (red line). Error bars for the observations are 2σ (Monge-Sanz et al., 2007).](image1)

![Fig. 2. Comparison of observed and modelled (red lines) mean age of air at latitudes of: (a) 5°S, (b) 40°N, and (c) 65°N. The lines with symbols represent observations: in situ SF$_6$ (dark blue line with triangles) (Elkins et al., 1996; Ray et al., 1999), whole air samples of SF$_6$ (purple line with squares for (b) panel, light blue line with squares outside vortex and orange line with asterisks inside vortex (c) panel) (Harnisch et al., 1999), and mean age from in situ CO$_2$ (green line with diamonds) (Boering et al., 1996; Andrews et al., 2001).](image2)

dinal slopes, and isentropic mixing, which tends to decrease the slopes (Plumb and Ko, 1992).

3.2 Validation of CO_2, CH_4, and SF_6 vertical profiles in the stratosphere

To evaluate the model’s ability to reproduce stratospheric transport, the simulated vertical profiles of CO_2, CH_4, and SF_6 were analysed and compared against balloon-borne observation data (Fig. 4). The observed VMRs were derived from six individual profiles of balloon-borne measurements performed by Takakiyo Nakazawa and Shuhji Aoki (Tohoku University) for Sanriku, Japan (39.17° N, 141.83° E) for 28 August 2000, 30 May 2001, 4 September 2002, 6 September 2004, 3 June 2006, and 4 June 2007, following the procedures described by Nakazawa et al. (2002). The vertical profiles were determined by averaging the modelled and observed concentrations taken for the same day and time. The error bars show the standard deviation. To calculate the mean profiles, we subtracted the annual growth rate of 0.23 pptv yr\(^{-1}\) (Stillier et al., 2008) for SF_6 and variable growth rates derived by Conway and Tans (2011) for CO_2 for the period 2001–2007. No correction is applied to the CH_4 concentration, because a slowdown in the CH_4 increase was observed in the stratosphere for the period 1978–2003 (Rohs et al., 2006).

In general, the NIES TM is able to capture the shape of a tracer’s vertical profile in the stratosphere. These profiles consist of several parts with different properties, such as: (1) weak gradients up to 70 hPa; (2) a large decrease of VMRs at heights between 70 and 50 hPa; (3) almost constant concentrations from 50 to 30 hPa; and (4) significant (especially for CH_4) gradients from 30 hPa upwards (Fig. 4).

The modelled profile of SF_6 is consistent with the observed profile up to 50 hPa and has a relatively large (~5%) positive bias above this level (Fig. 4a). SF_6 is a chemically inert tracer (in the troposphere and stratosphere), indicating that transport alone is responsible for the variation in its profile. The discrepancy between the observed and simulated vertical profiles is consistent with the underestimation of the age of air above 40 hPa in temperate and high-latitude zones, as discussed above.

In contrast, the CH_4 profile was found to have a strong negative bias (~5%) between 100 and 20 hPa (Fig. 4b), which disappeared with height. It would appear that a change in the CH_4 loss rate due to chemical reactions leads to less excessive destruction of methane and better agreement with observations above 20 hPa. SF_6 is not involved in any chemical reactions to compensate for the extra vertical transport in the UTLS region.

The simulated CO_2 vertical profile (Fig. 4c) overestimated the observed profile by 0.5% below 90 hPa and underestimated it by 0.5% above 90 hPa. The individual profiles used to derive the average profile were obtained at the beginning and end of the vegetation season; consequently, the modelled CO_2 profile shows a seasonal variation at the 140–100 hPa level. The large error bars become smaller with height, enabling an estimate of the seasonal variation of approximately 1–2 ppmv at 140 hPa. The spread of data in the profiles at about 1.5 ppmv at all levels is common for measured CO_2.

Thus, the simulated vertical profiles of CH_4 and SF_6 are generally within ~5% of the observed VMRs, while CO_2 profiles are within 1%. Given that the stratosphere only represents 15%–20% of the mid-latitude atmospheric column mass, these results are sufficient for this study. It is noted that the simulated CO_2 profiles have a smoother shape and show a better consistency with the observations, as the simulation was run for 9 years less than that for CH_4 and SF_6. This result indicates the ability of the model to reproduce vertical profiles of the tracers in the lower stratosphere more accurately for a relatively short-term period (about 10 years) than for a long-term period (about 20 years). This result reflects the fact that the model tends to overestimate tracer concentrations in the uppermost part of the domain, due to sparse grid layers in the lower stratosphere.

3.3 Validation of CO_2, CH_4, and SF_6 concentrations in the free troposphere

The ability of the NIES TM to simulate SF_6 and CO_2 in the near-surface layer and in the free troposphere was validated by Belikov et al. (2011) and Niwa et al. (2011). The inter-hemispheric gradients of SF_6 and CO_2, and vertical profiles and seasonal variations of CO_2 were evaluated against the GLOBALVIEW-CO2 and World Data Centre for Greenhouse Gases (WDCGG) observations, and against an aircraft measurement dataset of CONTRAIL (Niwa et al., 2011). Although the NIES TM’s performance in terms of transport, emission distribution and chemical loss, inter-hemispheric gradient, seasonal cycle, and synoptic variations in CH_4 were also quantified as part of the TransCom-CH_4 experiment.
Fig. 4. Comparison of observed and modelled concentration averaged for the period 2000–2007: (a) SF₆, (b) CH₄, and (c) CO₂. The observed VMRs were derived from six individual profiles of balloon-borne measurements over Sanriku, Japan (39.17° N, 141.83° E).

Fig. 5. Detrended seasonal cycle of surface CH₄ volume mixing ratio for GLOBALVIEW stations (corresponding TCCON stations in parentheses): (a) Baltik See (Bialystok); (b) Ocean Station M (Bremen); (c) Darwin (Darwin); (d) Hohenpeissenberg (Garmisch); (e) Izaña (Izaña); (f) Southern Great Plains (Lamont); (g) Baring Head Station (Lauder); (h) Pic Du Midi (Orleans); (i) Park Falls (Park Falls); (j) Pallas-Sammaltunturi (Sodankylä); (k) Ryori (Tsukuba); (l) Cape Grim (Wollongong); (m) Alert; (n) Mauna Loa; and (o) Syowa.
Given that one of the aims of this paper is to validate the modelled column-averaged concentration against ground-based FTS TCCON observations, we examined the variability of CH$_4$ concentrations at TCCON sites. We selected GLOBALVIEW-CH4 (GV-CH4) sites located near to TCCON stations and the following three sites additionally: Alert (82.45° N, 62.52° W), Mauna Loa (19.53° N, 155.58° W), and Syowa (69.00° S, 39.58° E) (Table 2). Time-series plots of the modelled near-surface CH$_4$ concentrations were compared with in situ observation data. For simplicity, we refer to the names of nearby TCCON stations with surface GV-CH4 station data. Fig. 5 shows time series of the CH$_4$ seasonal cycle for 1990–2008, which was manually adjusted by the annual mean concentration at the South Pole.

The simulations indicate that the model underestimated the near-surface seasonal cycle at northern high-latitudes. The model bias for Alert was 13.0 ppb versus 8.4 and 6.5 ppb for Mauna Loa and Syowa, respectively. A similar feature was observed for the trend of CH$_4$, for which the model bias decreased from the North Pole (0.5 ppb yr$^{-1}$) to the South Pole (0.1 ppb yr$^{-1}$) (Fig. 6).

Southern Australia and New Zealand are relatively isolated from large-scale CH$_4$ emission sources, and as a result there was some consistency between the modelled and measured values ($r = 0.87$–0.9 for Baring Head and Cape Grim) in capturing the small variability (amplitude of 30 ppb). As Darwin is located relatively close to the Asian tropics (Malaysia and Indonesia), which is marked by very high variations in CH$_4$ emissions and complicated meteorological conditions, the model was not able to reproduce the seasonal cycle as well at this site, compared with other sites.

The results for North America, whilst including a range of emission sources, indicated a similar agreement in the phase for Park Falls and Southern Great Plains (Lamont) ($r \sim 0.7$) and performed poorly in reproducing the growth rate, as the model underestimated the trends for both sites (Fig. 6). Mixed results were also found for the European sites: good agreement with observations was found for Pic Du Midi (Orleans) and Ocean Station M (Bremen), but poor agreement for Hohenpiensenberg (Garmisch) and Pallas-Sammaltunturi (Sodankylä). However, the worst agreement in the growth rate was found for Ryori (Tsukuba), where the model systematically underestimated the seasonal variations of the tracer.

We found very different model performance at remote sites such as Ocean Station M (Bremen), Izanå, Cape Grim (Wollongong), Baring Head (Lauder), Alert, Mauna Loa, and Syowa, where the model was generally able to accurately reproduce the phase of variations in surface concentrations (correlation coefficients of 0.85–0.95). For other sites (Park Falls, Pallas-Sammaltunturi (Sodankylä), Ryori (Tsukuba), and Southern Great Plains (Lamont)), however, where multiple emission sources are located close by and where local meteorology plays a major role, the model encountered difficulties in reproducing the complicated CH$_4$ surface concentrations.

### 3.3.2 Validation of CH$_4$ vertical profiles in the troposphere

To examine the variability of CH$_4$ in the near-surface layer and in the free troposphere, the VMRs simulated by the model were compared against aircraft observations performed by T. Machida (NIES) in 1993–2007 over Surugp, West Siberia. This location is marked by high CH$_4$ emissions from wetlands.
It is challenging to perform simulations of CH$_4$ in the northern high-latitude regions because of large uncertainties in emissions due to under-sampling of CH$_4$ concentrations over most regions, particularly where melting permafrost releases CH$_4$ (Zhuang et al., 2009). Despite this problem, the modelled and measured values are in good agreement above 1 km (Fig. 8). The model is less effective in reproducing the high variability in CH$_4$ concentrations in the near-surface layer and could not accurately simulate short-term variations. The averaged trends derived from the biases for the levels at 1, 3, and 7 km show similar values in all cases, in the range about 40 ppb depending on the season (Fig. 9). This result indicates balanced transport from the surface layer to the free atmosphere.
 troposphere due to the implementation of the JR-25/JCDAS meteorological data provided on the sigma-pressure levels.

The correlation coefficients between simulated and observed CH$_4$ values show an increase towards the free troposphere, from 0.19 for the 1-km level to 0.53 for the 7-km level, because vertical propagation decreases with height. While other factors are involved, changes in PBL height and associated variation in the rates of tracer redistribution from local sources to the free troposphere are important drivers of high variability in CH$_4$ VMR at GV-CH$_4$ sites with high emissions. Similar trends were obtained by Houweling et al. (2010) for four different transport models used to simulate XCO$_2$.

3.4 Validation of CO$_2$ and CH$_4$ column-averaged DMFs

The main goal of this paper was to validate the model’s ability to reproduce the CO$_2$ and CH$_4$ column-averaged dry-air mole fractions using observations from TCCON sites, which is a global network of ground-based high-resolution FTS recording direct solar spectra in the near-infrared spectral region (Wunch et al., 2011). The overall objectives of TCCON include improving our understanding of the carbon cycle and validating XCO$_2$ and XCH$_4$ retrieved from satellite observations.

For comparison, we selected simulated and TCCON XCO$_2$ and XCH$_4$ taken at around 13:00±1 h local time over TCCON sites for the period January 2009 to January 2011. Samples within this time-frame were collected for analysis, to assess the model’s performance within the LOSAT overpass interval. The following TCCON sites were selected: Bialystok (Poland, 53.22°N, 23.13°E); Bremen (Germany, 53.10°N, 8.85°E); Darwin (Australia, 12.42°S, 130.89°E); Garmisch (Germany, 47.48°N, 11.06°E); Izaña (Spain, 28.30°N, 16.50°W); Lamont (USA, 36.6°N, 97.49°W); Lauder (New Zealand, 45.04°S, 169.68°E); Orleans (France, 47.97°N, 2.11°E); Park Falls (USA, 45.95°N, 90.27°W); Sodankylä (Finland, 67.37°N, 26.63°E); Tsukuba (Japan, 36.05°N, 140.12°E); and Wollongong (Australia, 34.41°S, 150.88°E). For the Lauder site we used data from the 125HR spectrometer when available (February 2010–present) and data from the older 120HR spectrometer prior to February 2010.

To compare the modelled total column with measurements directly, it is necessary to consider the measurement averaging kernels. Averaging kernels describe the sensitivity of the retrieved total column to a perturbation in absorber abundance in a given layer of the vertical profile (Rodgers and Connor, 2003; Wunch et al., 2011). At present TCCON provides a single set of averaging kernels for CO$_2$ and CH$_4$, tabulated as a function of solar zenith angle (SZA), based on a subset of retrievals from the Lamont site (http://tccon.ipac.caltech.edu/tccon_aux_pub.html). Site-specific a priori profiles used in TCCON CO$_2$ retrievals were provided by each site PI. A single CH$_4$ a priori (independent of location and time) has been used in TCCON retrievals at all sites other than Darwin and Sodankylä. At these sites site-specific and time-independent CH$_4$ profiles are provided. The tabulated averaging kernels were interpolated to the SZA of the measurements and applied in the calculation of the CO$_2$ or CH$_4$ vertical column in accordance with Eq. (15) of Connor et al. (2008). The tracer vertical column abundances were then divided by the dry-air column abundance to calculate the column-averaged dry air mole fractions, denoted X$_y$ or DMF hereafter.

Due to the SZA dependence of the TCCON averaging kernels, the difference between total column concentrations calculated with and without averaging kernels is greatest for sites located farthest from the equator, Bialystok, Bremen and Sodankylä, which yield values in the range −0.6 to 2.0 ppm and −20 to 20 ppb for XCO$_2$ and XCH$_4$, respectively; the difference is smallest for the tropical and subtropical sites Darwin and Izaña, with values of −0.4 to 0.4 ppm and −5.0 to 5.0 ppb, respectively.

Time series of the model results and FTS data for XCO$_2$ and XCH$_4$ are shown in Figures 10 and 12, respectively. These figures were produced by manually adjusting the XCO$_2$ and XCH$_4$ model offsets (2.2 ppm and −32.0 ppb, respectively). The offsets were caused by the use of slightly out-dated fluxes for the simulations, the implementation of an averaging kernel, and misfit in the modelled vertical profiles. Thus, a XCH$_4$ offset may also be induced due to high uncertainty of OH and other species, which are responsible for CH$_4$ destruction in the atmosphere.

Matching the model’s mean CH$_4$ with the observations is achieved by adjusting either global total emissions or sinks, which both have large uncertainties (10–20 %, Patra et al., 2011). Small residual offsets can be adjusted by tuning global emissions, but long-term simulations are required to reach equilibration between sources and sinks. Adding a small 30 ppb offset to simulated results is nearly equivalent to the corresponding proportional change in the emissions fields on
the order of 2%. For CO₂, the corresponding bias correction is about 0.5 %.

For TCCON, the observation symbols and error bars represent the mean and standard deviations of the weighted average if more than one measurement within the 13:00±1 h local time was available. Note that gaps in the TCCON data time-series are due to cloud and instrumental issues.

### 3.4.1 Modelled XCH₄ compared with TCCON

#### FTS observations

Reproducing the CH₄ seasonal variation was a big challenge, because of its rather small amplitude and high scatter relative to the mean climatological value. As expected, the seasonal variation in XCH₄ over the Southern Hemisphere (i.e., Darwin, Lauder, and Wollongong) was weak (Fig. 10a, g, h) due to the smaller contribution of the local emissions; consequently, the model’s ability to reproduce the variation generally depends on reproducing of large-scale transport. The correlation coefficients for these sites are very similar (0.55, 0.58, and 0.66, respectively; Table 3).

In contrast, model performance at the Northern sites strongly depends on powerful local sources. The best correlation coefficients (in the range of 0.62-0.74) are obtained for Lamont, Bremen and Bialystok, where seasonal variation in XCH₄ has the highest amplitude. European sites show slightly large biases of 4.52, −8.80, and 20.91 for Bialystok, Orleans and Sodankylä, respectively. For Orleans, the correlation is rather weak (0.59, Table 3), whereas for the corresponding GLOBALVIEW station of Pic Du Midi it is rather...
When the polar vortex is also limited due horizontal grid resolution and a horizontal flux correction method implemented to NIES TM (Belikov et al., 2011). “Noise” appearing through the horizontal mass flux correction method may affect the vertical component of the wind vector and cause erroneously enhanced mixing and mass transport from the bottom of the atmosphere to the top (Belikov et al., 2011). In addition, NIES TM underestimates the age of air at high latitudes (Fig. 3c).

For Wollongong, the simulated results strongly underestimated the measurements (bias −11.05 ppb), as the FTS’
seasonal cycle amplitude was twice (Fig. 10l) the model value and twice that for other TCCON sites in the Southern Hemisphere. The reasons for this result remain unclear, although it may be relevant that Wollongong is located near major urban centers and sites of industrial activity, where emissions from coal mining are the largest source above background (Fraser et al., 2011).

The Izaña TCCON station is an oceanic site located on a small island and at high altitude (~2 km). The model’s grid is too rough to reproduce local emission and loss, or capture the topography. The model is not able to reproduce small-scale variations in concentration, and this results in a weak correlation (0.53) and large bias (9.05 ppb).

In general, the minimum and maximum bias between the two datasets is –8.80 ppb (–0.49 %) and 20.91 ppb (1.16 %), respectively. Figure 11 shows a scatter diagram of model XCH4 data versus ground-based FTS XCH4 data for 12 sites. The majority of points are within an interval of ±1 % of XCH4.

3.4.2 Modelled XCO2 compared with TCCON FTS observations and GECM

We compared XCO2 time-series with TCCON and constructed a 3-D CO2 climatology GECM (Gap-filled and Ensemble Climatology Mean) (Saito et al., 2011) (Fig. 12). The seasonally varying climatology in GECM was estimated by taking an ensemble of the various transport models in combination with the interpolated bias correction, using a data product based on in situ measurements in the troposphere (GLOBALVIEW-CO2, 2010) and the monthly vertical and latitudinal distribution of the ACTM-derived mean age of air in the stratosphere. Six transport models (ACTM, LMDZ4, NICAM, PCTM, and TM5), including the previous version of NIES TM (Belikov et al., 2011), participated in this study, but this is considered unlikely to seriously distort the results. The GECM seasonal cycle was nudged towards a seasonal cycle of the extended CO2 record (GLOBALVIEW-CO2, 2010) by filtering out the inter-annual anomalies and the synoptic-scale variability in the extended CO2 records using a curve-fitting procedure (Masarie and Tans, 1995).

The modelled XCO2 and GECM XCO2 time series show strong correlations with the TCCON data (correlation coefficients of 0.8–0.9; Table 3), as the seasonal XCO2 variation is stronger than the XCH4 cycle. Because of the use of actual meteorology and more up-to-date fluxes, the NIES TM described the seasonal variations slightly better for Bialystok, Bremen, Darwin, Lamont, Lauder, and Wollongong. Moreover, for all sites except Park Falls, Tsukuba, and Wollongong, the model bias was less than the bias for GECM. At other sites, comparisons of the model versus FTS and GECM versus FTS produced almost identical results.

The model shows quite good results in reproducing different seasonal cycles for all considered sites, including very steep decrease of XCO2 at Sodankylä during the growing season and almost flat profiles at sites in the Southern Hemisphere. Figure 13 shows a scatter diagram of model XCO2 data versus ground-based FTS XCO2 data. The minimum and maximum differences in the model data compared with the FTS data are –0.62 ppm (–0.16 %) and 1.21 ppm (0.31 %), respectively.

For XCO2 there are several events with only one FTS measurement taken at approximately 13:00 ± 1 h local time. Generally, the standard error in such cases is quite large especially for Lamont and Tsukuba (Fig. 12f, k).

4 Discussion

The model was able to reproduce the seasonal and inter-annual variability of XCO2 and XCH4 with correlation coefficients of 0.8–0.9 and 0.4–0.7, respectively. A small correlation was obtained for methane, due to the weak seasonal cycle of CH4 and a high scatter of XCH4 obtained from the ground FTS data within the selected interval (13:00 ± 1 h local time). The modelled time-series have quite small biases for all sites excluding Sodankylä, where model shows a large bias both for XCO2 and XCH4, 1.21 ppm and 20.91 ppb, respectively. Moreover, GECM results also show a large bias (1.22 ppm) for this site. Without Sodankylä’s data, the model bias is ±0.2 % and ±0.5 % for XCO2 and XCH4, respectively.

Model overestimation of CO2 and CH4 in the troposphere over Sodankylä during spring 2010 likely to be caused by errors in reproducing the polar vortex and requires further improvements in model parameterizations. Comparison with the other model simulations suggests the issue is not unique.
for NIES TM and difficult to attribute just to the use of average descent/cooling rates to calculate vertical transport in the stratosphere, as for example the online ACTM model with frequent update of the radiative transport has also been shown to possess large biases between the observed and modeled XCH$_4$ (Saito et al., 2012).

The tracer column-averaged dry-air mole fraction is a sensitive indicator of overall model performance, because it is relatively unaffected by changes in vertical transport and surface pressure, and shows minor spatial and temporal variations. As a result, the total column represents the model performance on a global scale. The XCO$_2$ and especially the XCH$_4$ scatter diagrams (Figs. 13 and 11, respectively) show balanced redistributions of tracer concentrations from the Northern Hemisphere, with high emissions to the Southern Hemisphere reproduced by the model. Moreover, the Darwin site shows vertical redistribution due to powerful tracer outflow from the PBL into the troposphere and the stratosphere,

---

**Fig. 12.** Time series of XCO$_2$ measured by FTS, modelled by NIES TM and derived from a 3-D CO$_2$ climatology GECM for the period January 2009 to February 2011, for the following stations: (a) Bialystok (Poland, 53.22° N, 23.13° E); (b) Bremen (Germany, 53.10° N, 8.85° E); (c) Darwin (Australia, 12.42° S, 130.89° E); (d) Garmisch (Germany, 47.48° N, 11.06° E); (e) Izaña (Spain, 28.3° N, 16.5° W); (f) Lamont (USA, 36.6° N, 97.49° W); (g) Lauder (New Zealand, 45.04° S, 169.68° E); (h) Orleans (France, 47.97° N, 2.11° E); (i) Park Falls (USA, 45.95° N, 90.27° W); (j) Sodankylä (Finland, 67.37° N, 26.63° E); (k) Tsukuba (Japan, 36.05° N, 140.12° E); and (l) Wollongong (Australia, 34.41° S, 150.88° E). The “error” for each symbol is a combination of the spread due to weighted averaging within the 13:00 ± 1 h local time interval and observation error.
was able to reproduce the variations in the surface concentrations more accurately \((r = 0.6–0.8)\) at sites located some distance away from multiple emission sources. For other sites, where high emissions and local meteorology play a major role, it proved difficult to reproduce the \(\text{CH}_4\) surface concentrations.

For measurements above 1 km, the model data are in good agreement with aircraft observations (1993–2007) over Surgut, West Siberia, which is an area with high emissions of methane from wetlands. However, the model was less effective in reproducing the high variability of \(\text{CH}_4\) concentrations in the near-surface layer and did not simulate short-term variations with any reasonable accuracy. These results are in agreement with the findings of Houweling et al. (2010), and highlight the importance of obtaining a realistic representation of PBL dynamics, especially in regions with high tracer emissions.

Convolved with scene-dependent instrument averaging kernels, XCO\(_2\) and \(\text{CH}_4\) were calculated from NIES TM tracer distributions and were compared with measurements acquired at TCCON ground-based FTS sites for the period from January 2009 to January 2011. The model was able to reproduce the seasonal and inter-annual variability of XCO\(_2\) and \(\text{CH}_4\) with correlation coefficients of 0.8–0.9 and 0.4–0.8, respectively. A comparison of modelled data and TCCON observations revealed that the model biases were ±0.2 % for XCO\(_2\) and ±0.5 % for \(\text{CH}_4\) without Sodankylä’s data.

In general, the overall performance of NIES TM at TCCON sites is similar to the performance of four transport models (IFS, LMDZ, TM3, and TM5) compared by Houweling et al. (2010) for XCO\(_2\) and to GEOS-Chem TM results published by Parker et al. (2011) for \(\text{CH}_4\). Although the focus of future work will be to further improve and validate XCO\(_2\) and \(\text{CH}_4\) simulations, the performance of the current model version is sufficient for use in evaluating satellite retrieval algorithms in areas not covered by ground-based FTS sites.

**Acknowledgements.** We thank T. Machida for aircraft observations of \(\text{CH}_4\) over Surgut (Russia); and A. E. Andrews, T. M. Hall, and D. W. Waugh for providing observation data of the mean age of air in the stratosphere. We also thank P. K. Patra and the TransCom-Ch4 and CONTRAIL TMI communities for model setups, initial profiles, and emission fluxes used in the tracer transport simulation. We also thank S. Oshchepkov for insightful discussions and suggestions regarding the manuscript. The meteorological datasets used for this study were provided by the cooperative research project of the JRA-25/JCDAS long-term reanalysis by the Japan Meteorological Agency (JMA) and the Central Research Institute of Electric Power Industry (CRIEPI). We also thank GLOBALVIEW-CO\(_2\)/CH\(_4\) authors. For calculations, we used the computational resources of the NIES supercomputer system (NEC SX-8R/128M16).

TCCON data were obtained from the TCCON Data Archive, operated by the California Institute of Technology from the website at http://tccon.ipac.caltech.edu/. US funding for TCCON
comes from NASA’s Terrestrial Ecology Program, grant number NNX11AG01G, the Orbiting Carbon Observatory Program, the Atmospheric CO₂ Observations from Space (ACOS) Program and the DOE/ARM Program. The Darwin TCCON site was built at Caltech with funding from the OCO project, and is operated by the University of Wollongong, with travel funds for maintenance and equipment costs funded by the OCO-2 project. We acknowledge funding to support Darwin and Wollongong from the Australian Research Council, Projects LE0669470, DP0879468, DP110103118 and LP0562346. Lauder TCCON measurements are funded by New Zealand Foundation of Research Science and Technology contracts C01X0204 and C01X0406. We acknowledge financial support of the Bialystok and Orleans TCCON sites from the Senate of Bremen and EU projects IMECC and GEOmon, as well as maintenance and logistical work provided by AeroMeteo Service (Bialystok) and the RAMCES team at LSCE (Gif-sur-Yvette, France) and additional operational funding from the National Institute for Environmental Studies (NIES, Japan).
