In situ engineering of urchin-like reduced graphene oxide-Mn 2O3-Mn3O4 nanostructures for supercapacitors

Abstract
We report the use of a spray pyrolysis method to synthesize high surface area (BET surface area of 139 m2 g-1) self-organized, micron sized urchin-like composites made up of reduced graphene oxide and needle-shaped manganese oxide (rGO-Mn2O3-Mn 3O4). Maximum capacitances of 425 Fg-1 at 5 mV s-1 from a three electrode set up and 133 Fg-1 at a current density of 0.2 Ag-1 were recorded using an asymmetric two electrode set up with graphene as the anode. The composite material also showed a capacitance retention of 83% over 1000 cycles. We attribute this remarkable performance to the high specific surface area due to the urchin-like hollow structures and synergy between the manganese oxide and reduced graphene oxide materials within the composite. Furthermore, this synthesis technique can be exploited further in the bulk synthesis of cost effective graphene-metal oxide hybrid materials for energy storage applications.

We report the use of a spray pyrolysis method to synthesize high surface area (BET surface area of 139 m$^2$ g$^{-1}$) self-organized, micron sized urchin-like composites made up of reduced graphene oxide and needle-shaped manganese oxide (rGO–Mn$_2$O$_3$–Mn$_3$O$_4$). Maximum capacitances of 425 F g$^{-1}$ at 5 mV s$^{-1}$ from a three electrode set up and 133 F g$^{-1}$ at a current density of 0.2 Ag$^{-1}$ were recorded using an asymmetric two electrode set up with graphene as the anode. The composite material also showed a capacitance retention of 83% over 1000 cycles. We attribute this remarkable performance to the high specific surface area due to the urchin-like hollow structures and synergy between the manganese oxide and reduced graphene oxide materials within the composite. Furthermore, this synthesis technique can be exploited further in the bulk synthesis of cost effective graphene–metal oxide hybrid materials for energy storage applications.

Introduction

From the assortment of metal oxides used as pseudocapacitors, RuO$_2$ stands out as the best performer.$^{1-3}$ However, due to high cost and environmental concerns, manganese oxide, which has a high theoretical capacitance of 1370 F g$^{-1}$, has been preferred.$^4$ Many attempts have therefore been made to synthesize manganese oxides through a host of techniques such as combined sonochemical and solvothermal, chemical precipitation,$^5$ sol–gel processes,$^6$ mechanical milling processes,$^7$ electrodeposition$^8$ and hydrothermal synthesis.$^9$ However, the preparation methods are less effective in controlling the crystal structure, microstructure and chemical state of manganese oxides.$^{10}$ In all these studies, the oxidation state of manganese has been reported to critically affect the electrochemical performance of the electrodes. The amount of research on Mn$_3$O$_4$ and Mn$_2$O$_3$ for supercapacitor studies has however been adversely affected due to their poor electrochemical activity. A transformation of $\gamma$-MnO$_2$ to $\alpha$-Mn$_2$O$_3$ and Mn$_3$O$_4$ by mechanical grinding has been found to cause a linear decrease in the specific capacitance as the amount of $\gamma$-MnO$_2$ decreased.$^8$ In a bid to improve the performance, researchers have synthesized Mn$_2$O$_3$–carbon aerogel and Mn$_3$O$_4$–graphene$^{12,13}$ composites although only a handful of such reports are available in literature. Recently, Wang and co-workers reported a solution based approach to synthesize Mn$_2$O$_4$–graphene nanocomposites with a maximum capacitance of 236.7 F g$^{-1}$ in 2 M NaOH.$^{14}$ Elsewhere, a maximum capacitance of 256 F g$^{-1}$ was reported in 6 M NaOH after the nanocomposites were synthesized by first mixing a graphene suspension in ethylene glycol with a MnO$_2$ organosol, followed by ultrasonication processing and heat treatment of the mixture.$^{15}$ Lee and co-workers also reported Mn$_3$O$_4$ nanorods mixed with graphene with a maximum capacitance of 121 F g$^{-1}$. All these studies however, were carried out in the three electrode set up without testing the practicality of device fabrication in a two electrode set up.

Depending on the method of preparation and conditions, a variety of nanostructures have also been reported. We are aware of the many reports on MnO$_2$ urchin-like structures in literature. These have been shown to possess high surface area and good electrochemical activity although their preparation time takes a considerabler long time when compared to the spray pyrolysis method.$^{17,18}$

In this work we use the in situ spray pyrolysis method to produce for the first time, hybrid 3D urchin-like architectures of Mn$_2$O$_3$ and Mn$_3$O$_4$ anchored on a highly conductive reduced graphene oxide support with improved electrochemical performance. A total specific capacitance of 425 F g$^{-1}$ and 133 F g$^{-1}$ in three-electrode and two-electrode asymmetric set ups were recorded in 1 M NaOH as an electrolyte respectively. In spite of the very limited time of heat treatment, the spray pyrolysis method proved to be effective in the reduction of graphene...
oxide (GO) to reduced graphene oxide (rGO), which offers a simple yet effective approach to design advanced graphene based hybrid materials with extraordinary capacitance. Due to the presence of rGO, high capacitance retention of 83% was observed over 1000 cycles.

The spray pyrolysis technique: while providing perfect homogeneity of the final products and productivity with industry up-scaling capabilities offers great flexibility regarding the type and use of initial solutions and/or suspensions. By controlling the fabrication process, it is possible to manufacture a wide range of materials with numerous shapes and structures. We therefore suggest that this method can be further exploited to fabricate a wide range of graphene–metal oxide–hydroxide materials for different applications in energy storage devices.

**Experimental procedure**

Two rGO–Mn$_2$O$_3$–Mn$_3$O$_4$ hybrid materials with different abbreviations are reported in this work as rGOMO1 and rGOMO2. These are a result of the spray pyrolysis of the following mixtures, 1 : 12 and 1 : 7 (GO : Mn(NO$_3$)$_2$·xH$_2$O), respectively. These ratios were chosen to study the electrochemical effect of GO loading in the composites.

**Synthesis of GO and hybrid materials**

The experimental setup and procedure for the synthesis of GO are similar to those described in our previous report on GO–MWNT hybrid material. The preparation of the composites is outlined in the schematic diagram in Fig. 1. To investigate the effect of adding GO to the manganese oxide we prepared the first material without any GO present. This material was prepared by adding 27.39 g of Manganese(II) nitrate hydrate (Mn(NO$_3$)$_2$·xH$_2$O, 98%, Sigma) powder into water resulting in a brown suspension, the same as Winkler test.

$$2\text{Mn(NO}_3\text{)}_2(s) + 3/2\text{O}_2(g) + \text{H}_2\text{O}(l) \rightarrow 2\text{MnO(OH)}_2(s) + 2\text{N}_2\text{O}_5(g)(1)$$

![Manganese(II) nitrate](image)

Fig. 1 Schematic diagram showing the experimental procedure for the formation of the Mn$_2$O$_3$–Mn$_3$O$_4$–rGO composites from manganese nitrate hydrate.

The red-brownish suspension was stirred for 30 minutes using a conventional magnetic stirrer and then sprayed at 600 °C in air into a vertical-type spray-pyrolysis reactor (note that this material was not mixed with graphene oxide). Following this, we prepared GO containing mixtures with varying amounts of GO with weight ratios of 1 : 12 and 1 : 7 (GO : Mn(NO$_3$)$_2$·xH$_2$O). Manganese(II) nitrate hydrate (Mn(NO$_3$)$_2$·xH$_2$O, 98%, Sigma) was diluted in a GO dispersion in water. The dispersion was stirred for 30 minutes using a conventional magnetic stirrer followed by spray-pyrolysis at 600 °C into a vertical-type spray-pyrolysis reactor to obtain rGOMO1 and rGOMO2.

**Electrode fabrication and analytical characterization methods**

X-ray diffraction experiments were performed at room temperature using high resolution X-ray diffraction system (GBC MMA X-ray diffraction (XRD) with Cu-Kz radiation). The elemental composition was characterised using the X-ray photoelectron spectroscopy (XPS, PHOIBOS 100 hemispherical analyser produced by SPECS Gmbh) with pass energy of 26.00 eV, 45° take-off angle and a beam size of 100 μm. The morphologies of the hybrids were examined by field emission scanning electron microscope (FE-SEM) using JSM 7500F, JEOL instrument. The specific surface area was determined by the BET method using the Nova 1000 gas sorption instrument. High-resolution transmission electron microscopy (HRTEM) was performed on the JEOL F3000 machine. For the three electrode set-up, the working electrode was prepared by coating the GOMO1 and rGOMO2 materials on to stainless steel sheets (1 cm × 1 cm) previously polished with sand paper and ultrasonicated in ethanol for an hour.

The electroactive material (rGOMO) were mixed with carbon black and PVDF binder at a mass ratio of 70 : 20 : 10 in an Agate mortar with (N-methyl pyrrolidinone) NMP solvent and ground to form a slurry.

This was then spread on to the polished stainless steel surface to achieve mass loadings between 1 and 2 mg and allowed to dry in a vacuum oven for 24 h. Electrochemical experiments were then performed at room temperature on the CH1660C (CH Instruments, Inc) electrochemical workstation using the three electrode system in a beaker type cell in 1 M NaOH. An Ag|AgCl reference electrode and a platinum foil counter electrode were used for the cyclic voltammetry (CV) over a voltage range of −0.2 to 0.5 V at various scan rates (5 to 100 mV s$^{-1}$). Electrochemical impedance spectroscopy (EIS) measurements were carried out between 10 kHz and 0.01 Hz using a 5 mV rms sinusoidal modulation.

To fabricate the positive electrode for the coin cell asymmetric setup, a slurry of the active material (in this case rGOMO1) was prepared as described above but this time coated onto the nickel foam substrate, with an average mass loading of ~1.4 mg cm$^{-2}$. The same procedure was followed for the negative electrode made up of graphene. The electrodes were then dried at 80 °C for 8 hours in a vacuum oven and pressed to a thickness of ~0.5 mm. These electrodes were assembled in a coin cell (LIR 2032) separated by whatman® filter paper with...
1 M NaOH as electrolyte. A combined mass of 3.6 mg was used for both electrodes with a mass ratio \(\text{m+/m–}\) of ~2. The cell was then tested using Galvanostatic charge–discharge measurements and EIS on an Autolab potentiostat PGSTAT 302N (Eco Chemie, Utrecht, The Netherlands) driven by the General Purpose Electrochemical Systems data processing software (GPES and FRA software version 4.9).

Results and discussion

Structural characterization

From the onset, it is interesting to note that a mixture of phases exists in the composites after spray pyrolysis. A solution of Mn\((\text{NO}_3)_2\cdot x\text{H}_2\text{O}\) without any GO, when sprayed, resulted in a mixture of oxides and hydroxides with different phases as shown in Fig. 2a. The limited time (less than 1s) at which the suspension was exposed to a maximum heat of 600 °C resulted in incomplete conversion to the more thermodynamically stable Mn\(_2\)O\(_3\) and Mn\(_3\)O\(_4\). We therefore refer to this mixture as manganese oxide–hydroxide. On the other hand, the XRD patterns of the hybrids made from nominal 1 : 1 and 1 : 7 (GO–Mn\((\text{NO}_3)_2\cdot x\text{H}_2\text{O}\)) ratios giving rise to rGOMO1 and rGOMO2 show mixtures of Mn\(_2\)O\(_3\) and Mn\(_3\)O\(_4\) with no traces of hydroxides after spray pyrolysis as the most intense peak of Mn Hydroxide (26.3) is not present in both rGOMO1 and rGOMO2 samples. The XPS spectrum of Mn region is also given in Fig. 2b. However it should be noted that due to the presence of a mixed valence state of 3 and 4, it is impossible to differentiate between hydroxide and oxide samples. These composites clearly demonstrate that the spray pyrolysis of MnO(OH)\(_2\) promotes the phase conversion according to the following pathway:

\[
\begin{align*}
\text{MnO(OH)\(_2\) & \rightarrow \text{Mn(OH)\(_2\)} \rightarrow \text{MnO(OH)} \rightarrow} \\
\text{MnO\(_2\) & \rightarrow \text{Mn\(_2\)O\(_3\)} \rightarrow \text{Mn\(_3\)O\(_4\) \quad (2)}
\end{align*}
\]

Nonetheless, the addition of graphene oxide (GO) to the suspension and spray pyrolysis results in the conversion of MnO(OH)\(_2\) to Mn\(_2\)O\(_3\) and Mn\(_3\)O\(_4\). XRD patterns suggest that at higher concentration of GO, characteristic peaks of Mn\(_3\)O\(_4\) emerge more sharply. Therefore, higher concentration of GO seems to increase the kinetics of phase transformation of Mn\(_2\)O\(_3\) to Mn\(_3\)O\(_4\) that usually needs heat-treatment at temperatures in excess of 800 °C.\(^{5,21}\)

In the case of spray pyrolysis, due to the very short reaction time, the co-existence of Mn\(^{2+}\) and Mn\(^{3+}\) favours the formation of hausmannite (Mn\(_3\)O\(_4\)),\(^{22,23}\) The addition of GO sheets, which exhibit oxygen functional groups in the form of carboxyl, hydroxyl or epoxy groups on their basal planes and edges and water molecules in between the GO sheets, can therefore promote faster kinetics of conversion to hausmannite (Mn\(_3\)O\(_4\)). These functional groups, which also contain hydrogen, might alleviate the decomposition of manganese hydroxide compounds and the reduction of Mn\(_2\)O\(_3\) to Mn\(_3\)O\(_4\). Therefore, the existence of the higher percentage of Mn\(_3\)O\(_4\) in rGOMO2 hybrid material compared to rGOMO1 can be attributed to the higher percentage of GO and consequently higher percentage of hydrogen containing functional groups. Field emission scanning electron microscopy (FE-SEM) was employed to investigate the morphology of the obtained samples. Fig. 3 shows FE-SEM micrographs of all three samples where unique urchin-like microstructures with manganese oxide needles are observed to grow radially from the rGO core of the hollow spheres.

Manganese oxides have the tendency to form nanorods or needle like structures.\(^{16,24,25}\) Though the formation mechanism

(a) Low magnification and (b) high magnification FE-SEM micrographs of manganese oxide–hydroxide with no rGO present showing an interconnected network of urchin like microstructures of the manganese oxide–hydroxide. Low magnification (c) and (d) high magnification FE-SEM micrographs of rGOMO1 composite showing a decreased length in nanorods. (e) A further increase in the amount of rGO resulted in the complete absence of metal oxide nanorods but a homogeneous distribution of nanoparticles (f) on the rGO surface for rGOMO2.
of the nanorods requires further investigation, the particles originating from the sprayed suspension are believed to orient themselves to form one-dimensional nanorods on the rGO sheets. Through oriented attachment along the side surfaces, 1D nanorods enlarge their diameter to become bulky nanorods in order to minimize the surface energy according to Li et al.26

In Fig. 3a and b, the nanorods between adjacent microspheres are observed to be entangled, creating a network on the electrode surface. However, higher amounts of GO sheets decrease the solubility of the Mn species, which is in agreement with the decrease in the length of nanorods upon increasing the percentage of GO in the solution. Moreover, the addition of GO dispersion (with pH of around 3–4) to manganese suspension increases the acidity of the suspension which results in proton chemisorption which in turn stabilizes the surface of small particles and limits the growth stage as observed in Fig. 3c and d. A combination of the nanoparticles and spherically shaped graphene oxide sheets provide a porous network on the electrode surface ideal for charge storage.

FE-SEM micrographs (In Fig. 3d and e) clearly suggest that an increase in the concentration of GO in rGOMO2, hinders further growth of manganese oxide needles upon keeping manganese oxide particles apart from each other. This is in agreement particularly with the BET results for the best performing manganese oxide particles apart from each other. This is in agreement particularly with the BET results for the best performing rGOMO1 observed to be 139 m² g⁻¹ while that of the manganese oxide–hydroxide sample was only 29 m² g⁻¹.

To further investigate the formation process, HRTEM was performed on the samples to reveal an aggregation of different primary nanoparticles in Fig. 4a. This suggests that the manganese oxide–hydroxide sample contains single crystal nanoparticles which are in good agreement with the formation mechanism suggested above. The attachment of these single crystal nanoparticles to form nanorods and further orientation of these 1D nanorods to form bulky nanorods is also illustrated in Fig. 4b. The combination of manganese oxide nanorods with graphene oxide sheets is shown in Fig. 4c suggesting the hollow nature of the spheres. Upon closer inspection it can be clearly seen in Fig. 4d, that the nanorods are actually composed of a few primary nanorods aggregated along the lateral faces.28

Typical C1s spectra of both as-prepared graphene oxide and spray pyrolyzed sample at 600 °C obtained by XPS are shown in Fig. 5. Deconvolution and curve fitting of C1s spectra were performed using CASAXPS software employing a Gaussian–Lorentzian peak shape after performing a Shirley background correction. The C1s spectra mainly consist of 5 individual peaks namely: carbon sp², carbon sp³, epoxy/hydroxyls, C–O groups and carboxylates. The significant increase in the ratio of carbon–carbon bonds to functional oxide groups (from 0.76 to 1.25) clearly suggests that spray pyrolysis can induce the graphene oxide to reduced graphene oxide transition in spite of the very limited time of heat treatment (less than 1 second). Cyclic voltammetry was used as the first diagnostic tool to electrochemically characterize the manganese oxide–hydroxide and rGOMO composites as shown in Fig. 6a. A large current separation was observed for the rGOMO1 electrode suggesting higher capacitance compared to rGOMO2 and manganese oxide–hydroxide electrodes.

The CV’s deviate from the rectangular shape expected for an electrical double layer capacitor (EDLC) due to the pseudocapacitance contribution by the manganese oxides which is known to add to the overall capacitance due to the variable oxidation states exhibited by manganese. Individually, Mn₃O₄ and Mn₂O₃ have been meagrely reported in literature as supercapacitor electrodes with low capacitance due to poor conductivity.5,28 However, a mixture of Mn₂O₃ and Mn₃O₄ mixed with multiwalled carbon nanotubes (MWCNT) has been reported by Lin et al. to give better performance due to the pseudocapacitance arising from electron transfer at Mn sites and EDCL contribution by the MWCNTs.28 Similarly, we observed the same phenomenon this time using rGO. The Mn³⁺ in Mn₂O₃ has been described as going through an oxidation reaction giving rise to one electron being transferred and attaining a valence state of Mn⁴⁺.28 Accordingly, the electrochemical reaction in eqn (3) is expected to take place during the charge–discharge process involving OH⁻ chemisorption/intercalation into Mn₂O₃ structure.5

\[
\text{Mn}[\text{Mn}]\text{O}_3 + \text{OH}^- \leftrightarrow 4\text{Mn}^{4+}[\text{Mn}^{3+}]\text{OH}^- \cdot \text{O}_3 + \text{e} \tag{3}
\]

---
While the energy storage mechanism of Mn$_3$O$_4$ supercapacitor electrode materials has been recorded previously as a proton–electron mechanism, the CV peaks in Fig. 6a cannot be assigned specifically to a particular phase since rGO also possesses some oxide groups on its surface that are capable of participating in redox reactions. However, the overall effect is an enhanced capacitance due to the pseudocapacitance effect arising from all the constituent materials in the composite. The following formula was therefore used to calculate the specific capacitance of the electrode materials at different scan rates.\textsuperscript{31}

\[
C = \frac{1}{mv(0.5 - (-0.2))} \int_{-0.2}^{0.5} I(V) dV
\]  

where \( m \) is the mass (g), \( v \) the scan rate (mV s$^{-1}$), \( i \) the current (A) and \( V \) the voltage. The highest capacitance at 425 F g$^{-1}$ was recorded for the rGOMO1, followed by 388 F g$^{-1}$ for the rGOMO2 and 336 F g$^{-1}$ for the manganese oxide–hydroxide at 5 mV s$^{-1}$. The highest specific capacitance for the rGOMO1 composite is much higher than that reported by Wang and co-workers for Mn$_3$O$_4$–graphene (256 F g$^{-1}$) in alkaline solution.\textsuperscript{15} Fig. 6b and c show the variation in specific capacitance with increase in scan rate.

As scan rate is increased, a drop in specific capacitance can be noted. This is due to the less effective interaction between electrolyte ions and the electrode at high scan rates. However, the 3D structure of the rGOMO1 material is essentially an ensemble of concealed interfaces which become accessible at low scan rates thereby increasing the electroactive surface area available for charge storage.\textsuperscript{14} We therefore established that at 5 mV s$^{-1}$, the chemisorption and/or intercalation of OH$^-$ into the microstructure is facilitated by the low scan rate hence the more pronounced peaks and higher capacitance. At high scan rates, the peaks become less pronounced (see Fig. 6b) due to the limited time for ions to reach some of the buried interfaces mentioned earlier.

Further tests to investigate mechanistic effects on the electroactive material such as ion transfer, conduction and capacitive behaviour were carried out using EIS. Fig. 6d shows comparative Nyquist plots for the three electrodes in the three electrode set-up. The Nyquist plot is made up of two regions: the high frequency and low frequency regions with each point on the Nyquist plot representing a particular measurement taken at a specific frequency. From the inset in Fig. 6d, the small semi-circle observed in the high frequency region is due to charge transfer resistance ($R_{ct}$) on the electrode/electrolyte interface. The intercept between the plots and the Z' axis represents the ohmic resistance ($R_s$). From the plot, the manganese oxide/hydroxide material is observed to have a small $R_{ct}$ (5.80 Ω) possibly due to the large number of nanorods that enhance the electrode surface area.\textsuperscript{33} An addition of rGO clearly enhances the conductivity of the composite as can be observed from the reduction in the $R_{ct}$ with increase in graphene oxide content in rGOMO2. The rGOMO1 hybrid material shows an $R_{ct}$ value of 4.53 Ω while that of rGOMO2 is only 3.7 Ω. rGO therefore acts both as a conductive support as well as an agent for the uniform dispersion of manganese oxide nanoparticles in the composite thereby enhancing charge transfer within both electrode materials.

The specific capacitance values calculated from the charge–discharge method using eqn (5) are in agreement with those from CV with the rGOMO1 achieving a specific capacitance of 356 F g$^{-1}$ followed by rGOMO2 with a specific capacitance of 249 F g$^{-1}$ and 178 F g$^{-1}$ for the manganese oxide–hydroxide at 0.35 Ag$^{-1}$.\textsuperscript{13}

\[
C = \frac{i(t) \times \Delta t(s)/m(g) \times \Delta E(V)}{1000}
\]  

where \( i \) is the discharge current in amperes, \( t \) the discharge time in seconds, \( m \) the mass of the active material in grams and \( \Delta E \) the potential window in volts.

From the values achieved, we can attribute the outstanding performance to the distinctive 3D network (combination of nanotubular whiskers and nanoparticles homogenously distributed on the surface of microparticles), synergy between metal oxide and the transition from GO to rGO after the spray pyrolysis. The rGO has been reported to be more conducting and also more capacitive than GO also showing good power capabilities.\textsuperscript{14}

\section*{Asymmetric supercapacitor}

An asymmetric supercapacitor was fabricated using the rGOMO1 as the cathode and graphene as the anode in 1 M NaOH electrolyte. A maximum value of 133 F g$^{-1}$ was recorded at 0.2 Ag$^{-1}$ using the charge discharge results in Fig. 7a and calculated using the formula:\textsuperscript{35}

\[
Cs = 4 \times \frac{i \times t}{V \times m_{\pm}}
\]  

where \( i \) is the current in Amperees, \( t \) the discharge time in seconds, \( V \) the voltage and \( m_{\pm} \) the total active mass of the positive and negative electrodes in grams. A factor of 4 was used...
to translate the specific capacitance of the asymmetric capacitor to that of the single electrode. The specific capacitance was also calculated for higher current densities yielding 115, 99, 87, 80, and 67 Fg\(^{-1}\) at 0.3, 0.5, 1, 2 and 5 Ag\(^{-1}\) respectively as shown in Fig. 6b. This is higher than the specific capacitance of 70 Fg\(^{-1}\) at 10 mV s\(^{-1}\) recorded for a graphene/MnO\(_2\)/CNT device fabricated by Cheng et al.\(^{37}\) These high values are due to the pseudocapacitance and EDLC contributions of the materials in the hybrid material as mentioned earlier. The shape of the charge–discharge curves in Fig. 7a slightly deviate from the linear profiles expected for EDLC due to the strong pseudocapacitance contribution by the combination of manganese oxide phases within the composite. This is in agreement with the CV’s in Fig. 6a which also show a distorted rectangular shape.

So far we have shown that the composite electrode material between manganese oxides and rGO results in enhanced capacitance. Following this, high energy and power densities of the asymmetric supercapacitor assembly should be expected due to the high surface area of rGO implying high power density while the manganese oxide has a high energy density. This synergy between the constituent materials results in a robust asymmetric device with an energy density of 9.07 W h kg\(^{-1}\) and a power density of 26.4 kW kg\(^{-1}\). These values were calculated using eqn 7 and 8 from the galvanostatic data.

\[
SE(W h/kg) = i(A) \times \Delta t(s) \times \Delta E(V)/m(kg)
\]

(7)

\[
SE(W h/kg) = \frac{SE}{t}
\]

(8)

where \(i\) is the current in amperes, \(\Delta t\), the discharge time in seconds, \(\Delta E\), the voltage window and \(m\), the mass in kg. A Ragone plot (see Fig. 7d) was generated which shows a clear relationship between the energy density and the power density as an efficient way to evaluate the electrochemical performance of supercapacitor device.

One of the characteristics that make supercapacitors more attractive energy storage devices when compared to batteries is the long cycle life of these devices. In light of this, a cycle life test was performed over 1000 cycles with the capacitance retention recorded at 2 Ag\(^{-1}\) using charge–discharge. A capacitance retention of 83% shown in Fig. 8 can be attributed to the presence of the more stable rGO support and graphene anode in the device. Carbonaceous materials are well known to possess remarkable cycling stability which renders the supercapacitor device appropriate for practical applications. Accordingly, the excellent interfacial contact between the Mn\(_2\)O\(_3\) and Mn\(_3\)O\(_4\) and formation of nanorods effectively prevent the agglomeration and restacking of graphene sheets thereby enhancing the electrochemical activity of the composites. Additionally, the presence of rGO in the final electrode materials assists in improving the conductivity of the poorly conducting Mn\(_2\)O\(_3\) and Mn\(_3\)O\(_4\), resulting in an enhanced electrical double layer capacitance to the overall specific capacitance, resulting in rapid charge–discharge process.

**Conclusions**

Hybrid structures of nanoneedle-shaped manganese oxide and spherical graphene oxide have been synthesized using an in situ spray pyrolysis strategy. The resulting urchin-like morphologies with high surface area (139 m\(^2\) g\(^{-1}\)) form a network on the electrode surface. The combination of reduced graphene oxide with manganese oxide clearly results in very good electrochemical performance (425 Fg\(^{-1}\) and 9.07 W h kg\(^{-1}\)) of the hybrid material. This is due to the electrical double layer capacitance from graphene oxide and pseudocapacitance from manganese oxide, which is in agreement with a recent report on an GO/MnO\(_2\) asymmetric capacitor.\(^{38}\) The overall capacitance retention (83%) over 1000 cycles is high enough for the material to be considered as a potential candidate for supercapacitor electrodes and other energy devices. The method and approach can be used for synthesis of other graphene–metal oxide electrodes for energy storage.
