Structural, metamorphic, and geochronological constraints on alternating compression and extension in the Early Paleozoic Gondwanan Pacific margin, northeastern Australia

Abstract
The Ross-Delamerian orogenic belt formed along the early Paleozoic active Pacific margin of the newly merged Gondwana supercontinent. In its northern-most segment in the Townsville region of northeastern Australia, we have identified a short contractional phase of the Delamerian orogeny in the Argentine Metamorphics postdating formation of a mafic breccia with a U-Pb zircon age of 500 ± 4 Ma. Contraction was followed by widespread inferred extensional deformation with formation of flat-lying foliation, domal features, and amphibolite grade and greenschist retrograde metamorphism all synchronous with latest Cambrian to Early Ordovician extensional backarc volcanism, sedimentation and intrusions. One of these intrusions gives a U-Pb zircon age of 480 ± 4 Ma. Foliation related to the extensional deformation is cross-cut by a late granodiorite dyke with a U-Pb zircon age of 461 ± 4 Ma. Late east-west contractional deformation affected the higher grade part of the assemblage. In contrast to the Ross-Delamerian orogenic belt in the Transantarctic Mountains and southeastern Australia, the orogenic belt in northeastern Australia was affected by a short episode of contraction at ∼495 Ma followed by long-lived backarc extension from ∼490 Ma to 460 Ma with subsequent contractional deformation.

Running Title: FERGUSSON ET AL.: COMPRESSION-EXTENSION IN AST AUSTRALIA
The Ross-Delamerian orogenic belt formed along the early Paleozoic active Pacific margin of the newly merged Gondwana supercontinent. In its northern-most segment in the Townsville region of northeastern Australia, we have identified a short contractional phase of the Delamerian orogeny in the Argentine Metamorphics postdating formation of a mafic breccia with a U-Pb zircon age of 500 ± 4 Ma. Contraction was followed by widespread inferred extensional deformation with formation of flat-lying foliation, domal features, and amphibolite grade and greenschist retrograde metamorphism all synchronous with latest Cambrian to Early Ordovician extensional backarc volcanism, sedimentation and intrusions. One of these intrusions gives a U-Pb zircon age of 480 ± 4 Ma. Foliation related to the extensional deformation is cross-cut by a late granodiorite dyke with a U-Pb zircon age of 461 ± 4 Ma. Late east-west contractional deformation affected the higher grade part of the assemblage. In contrast to the Ross-Delamerian orogenic belt in the Transantarctic Mountains and southeastern Australia, the orogenic belt in northeastern Australia was affected by a short episode of contraction at ~495 Ma followed by long-lived backarc extension from ~490 Ma to 460 Ma with subsequent contractional deformation.

1. Introduction
Subduction zone arc and backarc regions are characterized by the input of orogenic heat and are therefore more susceptible to contractional and extensional deformation than cratons and platforms [Thompson et al., 2001; Hyndman et al., 2005]. Extensional tectonics in continental backarc settings is associated with the development of metamorphic core complexes and associated low-angle normal faults as in the Aegean Sea [Lister et al., 1984; Ring and Layer, 2003] and the Basin and Range Province of southwestern North America [Crittenden et al., 1980]. In some regions extensional deformation has produced low-angle intense foliation without formation of low-angle normal faults as in Hercynian low-pressure amphibolite-grade metamorphics of the Pyrenees [Gibson, 1991] and greenschist to amphibolite grade rocks in the Yukon-Tanana terrane of Alaska [Pavlis and Sisson, 1993].

Contractional deformation in continental backarc regions is most exemplified by late Miocene to Recent foreland fold-thrust belts in the Andean backarc [Babeyko and Sobolev, 2005]. Alternating episodes of contraction and extension are widely recognized processes associated with convergent margins [e.g., Hall, 2002].

The Tasman Orogenic Zone of eastern Australia (Figure 1) has formed along the active Pacific-facing margin of East Gondwana [Cawood, 2005 and references therein] and has been categorized as an extensional accretionary orogen with multiple episodes of arc and backarc rifting interspersed with shorter episodes of contraction [Collins, 2002]. Cambrian to Early Ordovician development of the Tasman Orogenic Zone is related to the Ross-Delamerian orogenic belt that extends from northeastern Australia through the Adelaide Fold Belt of southeastern Australia and into Victoria Land and the Central Transantarctic Mountains of East Antarctica. Recognition of Delamerian orogenic events in northeastern Australia is only recent with K-Ar ages of about 500 Ma for metamorphism and deformation in the Anakie Metamorphic Group of central Queensland [Withnall et al., 1996] and U-Pb zircon ages of
about 507–455 Ma for granitic intrusions in the Charters Towers Province of north Queensland [Hutton et al., 1997].

We have re-evaluated the structure and metamorphism of, and obtained geochronological constraints for, the Argentine Metamorphics of the Charters Towers Province in northeastern Australia (Figure 1). The new data enable us to establish the tectonic history for this part of the Ross-Delamerian orogenic belt. A significant episode of post-contraction extensional deformation has been recognized in the region, and building on prior work [Fergusson et al., 2005] we place this event in the context of extensional events associated with Ross-Delamerian orogenesis as a whole. Cambrian to Early Ordovician tectonism for the Ross-Delamerian orogenic belt has been characterized by broad-scale contemporaneity of alternating extensional and contractional episodes [Foster et al., 2005; Squire and Wilson, 2005]. The tectonic synthesis presented herein incorporating data from the northern Tasman Orogenic Zone confirms this alternation of tectonic mode but indicates more complexity in space-time patterning than previously recognized for the East Gondwana margin during 50 Ma of plate convergence and subduction in the Late Cambrian through the Middle Ordovician.

2. Regional Setting

The northern Tasman Orogenic Zone consists of a Neoproterozoic to Early Paleozoic assemblage developed in a northern equivalent of the Adelaide Fold Belt known as the Thomson Fold Belt (Figure 1). Much of the Thomson Fold Belt is in the subsurface but exposure occurs in the Anakie Inlier and the Charters Towers Province of central and north
Queensland respectively [Murray and Kirkegaard, 1978]. Early Paleozoic rocks also occur in parts of the adjoining outboard Hodgkinson – Broken River Fold Belt but this belt is dominated by Middle and Late Paleozoic rocks and it should be kept separate from the Thomson Fold Belt [cf. Glen, 2005]. The Charters Towers Province of Henderson [1980] has the most extensive and diverse rock systems of Ordovician age or older in the northern Tasman Orogenic Zone. These older rocks include a belt of generally little deformed Late Cambrian – Early Ordovician volcano-sedimentary rocks of the Mount Windsor Subprovince [Henderson, 1986] and numerous granitoid phases of the Ravenswood Batholith and Fat Hen Creek Complex that are largely Ordovician (507–455 Ma) and separated as the Macrossan Igneous Province by Hutton et al. [1997] on the basis of age. Dispersed metamorphic tracts form country rock to the Ordovician granitoids (Figure 2). They include the Cape River, Running River, and Argentine Metamorphics as well as some smaller screens within the Ravenswood Batholith. Such metamorphics are the lowest structural unit in the Charters Towers Province and consist of an assemblage of low to high-grade metasedimentary units with associated foliated igneous rocks. Detailed geochronology is sparse [e.g., Fergusson et al., 2005]. An Early Silurian orogenic event has been recognized for the southwestern Hodgkinson – Broken River Fold Belt [Arnold and Henderson, 1976], affecting diverse rock systems that include Early Ordovician siliceous turbidites, Late Ordovician volcanic and volcanioclastic rocks, and mafic-ultramafic rocks of uncertain age [Withnall and Lang, 1993]. The Greenvale Province occurs west of the Hodgkinson – Broken River Fold Belt (Figure 2) and contains tectonized Early Paleozoic rock assemblages [Nishiya et al., 2003]. The Anakie Metamorphic Group, extensively exposed as a basement inlier surrounded by interior basins of the northern New England Fold Belt (Figure 1), is considered to represent an extension of the Delamerian
orogeny in northeastern Australia [Withnall et al., 1996; Fergusson et al., 2001]. Detrital zircon age signatures indicate that these metamorphic units of the Thomson Fold Belt include a latest Neoproterozoic passive margin succession and a younger, Cambrian stratigraphic unit [Fergusson et al., 2001, 2007].

The Argentine Metamorphics [Withnall and McLennan, 1991; Hutton et al., 1997] are a multiply deformed metasedimentary and metaigneous assemblage that forms many inliers west of Townsville with the most significant being at Laroona (Figure 2) and in the Argentine area (Figure 3). They are non-conformably overlain by, and faulted against, Devonian-Carboniferous volcanic and sedimentary rocks of the Burdekin Basin. Deformation is particularly evident in the sedimentary units of the lower less volcanic part of the Burdekin Basin with syn-depositional extensional structures (half-graben and graben fill) and later contractional structures although usually of low strain and associated with varying fold trends [Hutton et al., 1997]. Dips in these rocks are typically around 20–40° and it is likely that the regional dips of the main foliation in the Argentine Metamorphics have been steepened during contractional and/or extensional deformation of the overlying Burdekin Basin. Abundant Carboniferous to Permian granitic intrusions and associated volcanic rocks are widespread in the Charters Towers Province.

3. Argentine Metamorphics

Metasedimentary rocks dominate the assemblage with biotite schist, phyllite, minor graphitic schist, quartzose metasandstone, quartzite, para-amphibolite and calcsilicate rock. Metaigneous lithologies include foliated to massive amphibolite, mafic schist, serpentine,
biotite/muscovite orthogneiss, migmatite and sills and dykes of leucogranite. We have conducted detailed traverses across the unit mainly in the Argentine area (Figure 3) leading to some revision of previously established units [Withnall and McLennan, 1991]. Major subdivision is into higher grade and lower grade metamorphic packages. The higher grade rocks occur in the northwestern to eastern part of Figure 3 and are dominated by paragneiss and schist (Amg on Figure 3), including abundant quartzose metasandstone with granitic veins, with adjoining orthogneiss (Amo). The lower grade package dominated by biotite schist, quartzite (Ams) and mafic schist occurs in the southwestern part of Figure 3 and is also mapped in other inliers of the Argentine Metamorphics [Withnall and McLennan, 1991] such as at Laroona to the northwest (Figure 2). In the upper Cattle Creek area higher grade rocks surround a core of phyllite that also contains some mafic schist (Figure 3). Ravenswood Granodiorite has intruded metasedimentary gneiss and schist units to the southeast (Figure 3) and is strongly foliated.

The primary sedimentary assemblage consisted predominantly of pelite interbedded with quartz-intermediate sandstone, quartz-rich sandstone, and variably calcareous lithologies that presumably are of marine origin. The small size of some amphibolite bodies suggests that these rocks most likely represent a hypabyssal basic igneous assemblage whereas other amphibolites may represent either a volcanic or a volcanioclastic protolith. Geochemistry presented by Withnall and McLennan [1991] and summarized by Hutton et al. [1997] in addition to further analyses on samples collected during this study [Geological Survey of Queensland, 2005] suggest that two suites of mafic rocks are present in the Argentine Metamorphics. The mafic schist associated with the low-grade package (Ams) shows enrichment in high-field-strength elements similar to alkali basalts in intraplate settings, whereas the amphibolite in interlayered schist and amphibolite (Amsa) show a relatively un-
enriched pattern and have tholeiitic affinities. Withnall et al. [1995] found a similar divergence in geochemical affinities between mafic suites in the Anakie Metamorphic Group.

3.1. Structure

The Argentine Metamorphics are affected by up to four deformations whose characteristics are given in Table 1 with orientation data shown in Figures 3–5. The highest-grade metamorphic rocks along the abandoned Greenvale-Yabulu railway in the western part of the Argentine area have the greatest structural complexity whereas the lower grade rocks are simpler with the main foliation dipping away from the core of higher grade rocks (Figures 3 and 4). Lower grade rocks show two main deformations with $S_1$ foliation preserved in microlithons associated with the regional $S_2$ (Figure 6a). Little is known about $D_1$ due to strong overprinting by the $D_2$ deformation. $D_2$ formed the regional foliation ($S_2$) that mainly dips moderately to gently southwards (Figures 3, 4 and 5a). Lithological layering is commonly transposed subparallel to $S_2$ and tight folds abound (Figure 6b).

In the highest-grade rocks along the abandoned Greenvale-Yabulu railway in the western part of the Argentine map area, microlithons in the main foliation are rare but occur in some exposures. Banded orthogneiss in some zones of outcrop shows fine-scale (0.5–1cm) anastomosing layering indicative of high shear strain (mylonitic) fabrics and sporadic, narrow (1–2 cm) zones of intense shear characterized by grain size reduction. The main foliation ($S_2$) is more variable in orientation than at lower grades (Figure 3) due to overprinting $D_3$ and $D_4$ deformations. The $D_3$ deformation is mainly restricted to the area around the locality of Argentine (Figure 3) and is manifest as tight to close, recumbent to gently inclined folds (Fig. 6c). The $D_4$ deformation is particularly prominent in the abandoned Greenvale-Yabulu
railway cuttings in the western part of the Argentine map area and has abundant F_4 folds formed under east-west contraction.

The higher grade zone contains a domal feature defined by the orientation of S_2 in upper Cattle Creek with an inner core of retrogressed lower grade rocks dominated by phyllite with some mafic schist (Figures 3 and 4). In the core of the dome, foliation is nearly flat-lying (Figure 5h). The phyllite is characteristically fine-grained in contrast to surrounding units and contains widespread evidence for shearing such as folded lineations within the plane of the foliation, S and C planes, and shear bands (Figure 6d). The fine grain size is attributed to dynamic recrystallisation that accompanied shearing. Metamorphism has continued beyond the major interval of shearing allowing recovery of grains and the development of strain-free granoblastic aggregates in quartz-rich layers in the phyllite. All shear sense criteria are consistent with top to the north and northeast.

Within deformed granitic plutons and coarser grained amphibolites intruding the Argentine Metamorphics, a single main foliation is developed that has an orientation coplanar with S_2 in the adjacent country rocks. The foliation has clearly formed by ductile deformation and in granites is defined by aligned quartz, feldspar and clots of mainly chlorite that has replaced the main mafic minerals.

3.2. Metamorphism

A general amphibolite grade peak of metamorphism for the Argentine Metamorphics is indicated by garnet, and typically altered sillimanite and uncommon andalusite in pelitic rock units and widespread hornblende and minor diopside in amphibolite, mafic schist and calc-silicate rocks. In pelitic and psammopelitic rock types, micas and elongate quartz are aligned
along both $S_1$ and $S_2$ foliations indicating metamorphism accompanying these deformations. In higher grade rocks $S_1$ is difficult to recognize in most outcrops and sillimanite, usually replaced by muscovite, is aligned in the $S_2$ foliation but the relationship to $S_1$ is unknown. Andalusite occurs in slightly lower grade rocks; it is also retrogressed and is aligned in the $S_2$ foliation. Retrogression is widespread with development of muscovite and chlorite. Idioblastic garnets up to 2 mm across are locally developed in higher grade psammopelitic gneisses rocks but lack inclusion trails. In most amphibolites a single foliation is defined by aligned hornblende with elongate plagioclase and quartz (Figure 7). More rarely in some amphibolites two foliations ($S_1$, $S_2$) defined by elongate hornblende occur. Amphiboles mainly have ferro-hornblende and ferro-tschermakite compositions. Some lithologies in thin section show relict igneous clinopyroxene cores with amphibole rims, or clinopyroxene partially replaced by amphibole. Retrogression is also common in amphibolite and in some rocks actinolite and tremolite have completely replaced all hornblende and clinopyroxene. Retrogression has been partly synchronous with the second deformation in the lower grade rocks and the occurrence of randomly oriented flakes of muscovite across foliation in some pelitic schist is consistent with greenschist facies metamorphism continuing after the main phases of ductile deformation. The development of andalusite and the lack of kyanite are consistent with low-pressure metamorphism. Variation in the metamorphic grade is indicated by the widespread development of migmatitic segregations and some pegmatitic veins in higher grade rocks and their absence from lower grade rocks. Temperatures of crystallization were determined from selected ilmenite-bearing amphibolites and calc-silicate rocks using the edenite-richterite geothermometer of Holland and Blundy [1994] and a method based on the TiO$_2$ content of amphibole devised by Foster
Hornblende and plagioclase were analyzed using the JEOL JXA-8200 electron probe microanalyser at James Cook University (mineral compositions and a full list of calculated temperatures are available in the auxiliary materials). Temperature estimates (Table 2) based on the TiO₂ thermometer of Foster [in press], generally indicate metamorphic temperatures in the range of 540–590°C, consistent with lower to middle amphibolite facies temperature estimates derived from thermodynamic considerations of the mineral assemblages represented in the Argentine Metamorphics [see Spear, 1995]. However, temperature estimates in the range of 730–770°C obtained from four samples are considered to reflect relict igneous mineral compositional signatures which were not reset during metamorphism. These samples are all medium-grained amphibolite with intergranular igneous textures and phenocrysts ranging to 2 mm or more in diameter, and almost certainly are metaplutonic rocks. In addition, three samples returning temperature estimates of 625–645°C represent incomplete metamorphic resetting of igneous signatures.

With respect to the Holland and Blundy [1994] edenite-richterite geothermometer, only three samples (A9, AM43 and AM91) returned estimates (527–583°C) that are plausible as metamorphic temperatures with estimates for the other 11 samples anomalously high (generally >655°C) with respect to the observed mineral assemblages, suggesting that the method is not usefully applicable to the mineral chemistries of the rocks examined. This may be due to the high iron content of the hornblends analysed (generally 16–22% FeO), and reflect difficulty in accurately assigning Fe₂O₃ contents calculated on the basis of stochiometry applied to microprobe analyses, with implications for other site fraction allocations [see Holland and Blundy, 1994]. Alternatively, these amphibolites may have formed from metamorphism of basic igneous rocks that intruded late in the metamorphic episode and therefore were only partially equilibrated during metamorphism.
4. Geochronology

4.1. Zircon U-Pb Age Data

4.1.1. Methods

Samples were selected for U–Pb zircon dating by the Sensitive High Resolution Ion Micro-Probe (SHRIMP at the Research School of Earth Sciences, Australian National University). Zircons were separated from samples and cathodoluminescence images (CL) were taken to enable selection of zircons for analysis on SHRIMP (Figure 8). Analytical techniques followed methods given by Williams [1998] and references therein. Analyses consisted of six scans through the mass range and results have been calibrated relative to 1099 Ma Duluth Gabbro reference zircons [Paces and Miller, 1993]. Data have been reduced using the SQUID Excel Macro of Ludwig [2000] and plotted using ISOPLOT/EX [Ludwig, 1999]. All the areas analysed are <800 Ma and so common Pb correction has been made using the measured $^{207}\text{Pb} / ^{206}\text{Pb}$ and $^{238}\text{U} / ^{206}\text{Pb}$ ratios as discussed in Williams [1998]. Therefore, only radiogenic $^{206}\text{Pb} / ^{238}\text{U}$ ratios and ages are reported in Tables 3–5. Some of the areas analysed are considered discordant, having lost radiogenic Pb. Interpreted discordant analyses have been excluded from weighted mean $^{206}\text{Pb} / ^{238}\text{U}$ age calculations (Figure 9).

4.1.2. Results

Sample IWAM162D is a metaigneous clast within an amphibolite that comprises many fragments and was probably a primary mafic volcanic breccia. It is from Towns Creek in the Laroona area (Figure 2, 0393360 7861810 Ewan 8059 1:100 000 topographic map, map datum AGD66) and was selected to provide a maximum age of deposition. The sample is very fine-grained with quartz, plagioclase and minor biotite. The zircons from this clast are coarse
sub to anhedral grains for which CL scanning electron microscope images show broad oscillatory zoning (Figure 8) as typical of those separated from less silicic igneous rocks such as diorite [Hoskin, 2000]. The zircon has been affected by post magmatic effects and there are thin (≤ 5 µm in width) crack-seal veinlets filled with secondary zircon, too narrow to be analyzed at this time. Twenty one areas on zoned magmatic zircon have been analyzed and they all cluster within uncertainty of the Tera-Wasserburg Concordia curve, with the age distribution forming a simple bell-shaped curve (Figure 9a, Table 3). All 21 analyses are within analytical uncertainty giving a weighted mean $^{206}$Pb/$^{238}$U age of 500 ± 4 Ma (2σ; MSWD = 1.15). This provides an estimate for the maximum time of formation of the breccia.

Sample HR1 is from a substantial body of coarse-grained, foliated granodiorite cropping out in the southeastern extremity of the Argentine area (see Figure 3, 0431950 7843600 Dotswood 8158 1:100 000 topographic map) and was selected to provide a maximum age of regional S2. Foliation is defined by elongate plagioclase and quartz with seams of chloritized mafic minerals and is coplanar with the dominant (S2) fabric in the Argentine Metamorphics to the north. The zircons from this sample are euhedral grains with simple oscillatory zonation under CL imaging (Figure 8b). Twenty zircon grains have been analyzed (Figure 9b, Table 4); two are discordant and two others are significantly enriched in common Pb. On the probability density plot it can be seen that there is a single dominant age peak and the weighted mean for these 13 analyses is 480 ± 4 Ma (2σ; MSWD = 0.49). This is interpreted as the age of intrusion. Pervasive fabric development within the pluton suggests that the D2 deformation was active whilst elevated temperatures and thermal weakening pertained during its cooling history at a time little separated from that of emplacement.

Sample AM77 is from a medium-grained granodiorite dyke exposed in a cutting on the derelict railway line south of Cattle Creek (Figure 3, 0422500 7850410 Rollingstone 8159
1:100 000 topographic map) with weak S₄ but lacking the dominant foliation of the host paragneiss. It contains altered plagioclase, quartz, minor biotite, rare garnet, scattered large flakes of muscovite, and smaller flakes of muscovite replacing biotite and was selected to provide a minimum age for S₂. The zircons from this sample are heterogeneous and have complex internal structures. The CL images show a wide range of inherited components forming the central areas to these grains, ranging from zoned magmatic to metamorphic discrete areas (Figure 8c). Many grains have a dark CL, euhedral tip that is interpreted as having formed at the time of intrusion of this granodiorite dyke. For the current study 25 areas have been analyzed on 23 zircon grains, with the late stage dark CL tips being the target of these analyses even though some of the areas are not ideal due to alteration. A number of the areas analyzed are significantly enriched in common Pb (analysis 16.1 Table 5) or are interpreted to have lost radiogenic Pb (analyses 3.1, 5.1, 21.1 and 23.1). On the relative probability plot there is a dominant age peak that is skewed towards the younger side reflecting the interpreted radiogenic Pb loss. A weighted mean for 13 analyses in this dominant age peak gives an age of 461 ± 4 Ma (2σ; Figure 9c, Table 5) and is considered to date the time of magmatic zircon overgrowth. Thus intense deformation was substantially completed by about 460 Ma.

4.2. ⁴⁰Ar/³⁹Ar Age Data

4.2.1. Methods

Sample AM89, an amphibolite (Figure 7) from the mafic schist/amphibolite unit in the northern part of the Argentine area (~2 km north of map boundary near point A in Figure 3, 0420740 7856933 Rollingstone 8159 1:100 000 topographic map) was analyzed by the ⁴⁰Ar/³⁹Ar method to provide a constraint on metamorphism of the Argentine Metamorphics.
Amphibole in this sample has a ferro-hornblende composition for which microprobe analyses applied to geothermometry (Table 2) suggests retention of igneous compositional characteristics. It was separated using conventional magnetic and heavy liquid separation methods. Hand picking of the amphibole enabled a purity of greater than 99% to be achieved. 

$^{40}$Ar/$^{39}$Ar analyses were carried out at the School of Earth Sciences, The University of Melbourne following procedures described previously by Reid et al. [2005]. The sample was irradiated along with flux monitor Hb3gr hornblende (age = 1072 Ma; [Turner et al., 1971; Roddick, 1983]) in the McMaster University reactor, Canada. K$_2$SO$_4$ and CaF$_2$ salts were included in the irradiation package to determine interference correction factors. After irradiation, a weighed aliquot of the sample was loaded into a tin foil packet and step-heated in a tantalum resistance furnace. $^{40}$Ar/$^{39}$Ar step-heating analyses were conducted on a VG3600 mass spectrometer, utilising a Daly detector. Mass discrimination values were monitored by analyses of purified air aliquots. Correction factors for interfering isotopes are: ($^{36}$Ar/$^{37}$Ar)$_{Ca} = 2.79 (±0.05) \times 10^{-4}$; ($^{39}$Ar/$^{37}$Ar)$_{Ca} = 6.82 (±0.05) \times 10^{-4}$; ($^{40}$Ar/$^{39}$Ar)$_{K} = 0.0286 ± 0.0006$. Decay constants are from Steiger and Jäger [1977].

### 4.2.2. Results

Amphibole from sample AM89 yielded a pseudo-plateau age of 438.7 ± 2.6 Ma (2σ; including J-error; MSWD = 0.79) that includes 46% of the $^{39}$Ar (Figure 10, Table 6). This age is similar to the mean value of 442.3 ± 5.0 Ma (2σ), obtained for all intermediate to high temperature steps (1040 – 1450°C). Given that the amphibole composition is considered to reflect igneous crystallization (Table 2) followed by strain during D$_2$ deformation (Figure 7), which is constrained at between 460 and 480 Ma by the U-Pb data, the ~440 Ma result is interpreted to indicate metamorphic cooling of the sample through the amphibole closure temperature of ~500°C [e.g., McDougall & Harrison, 1999].
5. Discussion and Conclusions

5.1. Tectonic Development of the Argentine Metamorphics

Depositional attributes of the Argentine Metamorphics are poorly defined due to the intensity of deformation and metamorphism. Deposition of the upper lower grade part of the unit is probably Late Cambrian with a maximum limit to sedimentation and volcanism given by the $500 \pm 4$ Ma clast from the Laroona area. On the basis of the youngest coherent group of detrital zircons ages other late Middle to Late Cambrian quartzose successions are inferred for the Thomson Fold Belt. These include the Halls Reward Metamorphics of the Greenvale Province [Nishiya et al., 2003], located 170 km west-northwest of the Argentine Metamorphics, and the upper part of the Anakie Metamorphic Group in addition to a late Neoproterozoic unit in the lower Anakie Metamorphic Group [Fergusson et al., 2001], which occur $300-400$ km south of the Charters Towers Province.

Structural relationships between the higher grade and the lower grade rocks have been disputed. Hammond [1986] inferred a detachment zone between these two packages but the mapping of Withnall and McLennan [1991] and our work does not support this interpretation and instead a gradational relationship is recognized. The style of early deformation in the Argentine Metamorphics is obscured by the intensity of the $D_2$ deformation but given the apparent steep orientation of the $S_1$ foliation, it is considered to reflect contractional deformation. Timing of this event is bracketed between the inferred depositional age of the upper Argentine Metamorphics and the intrusion of the adjoining granodiorite pluton which
was synchronous with the D₂ deformation (Figure 11). Intense D₂ deformation was
accompanied by this intrusion at 480 ± 4 Ma and postdated by a granodiorite dyke with an
age of 461 ± 4 Ma. D₃ and D₄ deformations are only found in the higher grade part of the
Argentine Metamorphics. D₄ deformation consists of upright, northerly trending structures
reflecting east-west contraction presumably accompanied by uplift and erosion and could be
responsible for the ⁴⁰Ar/³⁹Ar cooling age of ~440 Ma on amphibole from amphibolite from
the structurally lower part of the assemblage. In contrast both D₂ and D₃ deformations
developed with recumbent to near recumbent attitudes and therefore largely reflect vertical
flattening (see below). Our interpretation is that amphibolite facies metamorphism
accompanied deformation with high temperatures persisting in the higher grade part of the
unit up to the D₄ deformation. A clear spatial relationship exists between the higher grade
core of the Argentine Metamorphics dominated by partially sheet-like orthogneiss and rocks
with abundant granitic segregations and veins implying that the locally higher grade
conditions reflect heat advection associated with synchronous intrusions as widely
documented in low-pressure metamorphic terrains [Richards and Collins, 2002; Caggianelli
and Prosser, 2002].

5.2 Role of Extensional Deformation

The role of extensional deformation in the uplift of high pressure and ultra-high
pressure metamorphic rocks and in the exhumation of metamorphic core complexes is well
documented in the literature [e.g., Crittenden et al., 1980; Ring and Layer, 2003]. The
Argentine Metamorphics lack evidence for an extended brittle hanging wall block and no
detachment fault has been recognized. Suggestions of a detachment fault between the lower grade and higher grade packages of rocks are not consistent with the widespread development of amphibolite facies metamorphism throughout the unit. An extensional origin for the D2 deformation accounts for the original flat-lying orientation of the main S2 foliation with abundant recumbent folds and extension within the foliation plane consistent with vertical flattening. Comparable flat-lying foliation is a feature of regional developed amphibolite and greenschist facies rocks of the Yukon-Tanana Terrane of east-central Alaska [Pavlis and Sisson, 1993] and attributed to extensional tectonics. Sub-horizontal foliation in higher grade rocks has also been widely attributed to vertical flattening of the lower crust during extensional tectonics [Sandiford, 1989; Harris et al., 2002].

A problematic feature of the Argentine area is the development of the Cattle Creek dome and its association with the D3 deformation which is particularly evident on the southern flank of the dome. The domal feature is also shown by the orientation of bedding in the Devonian sedimentary cover (Figure 3) and is therefore partly due to post-Devonian upper crustal deformation. D3 structures are recumbent as inferred for development of the D2 deformation, indicating continued vertical flattening. For new recumbent folds to develop during D3 the main S2 foliation must have been tilted prior to the imposition of strain so that the S2 foliation lay in the shortening rather than extending field during progressive deformation. This could have occurred only if the Cattle Creek dome developed during continued vertical flattening that generated the D2 and D3 deformations. Such doming may have formed as result of largescale boudinage and/or doming due to intrusion of an underlying granitic and/or mafic mass synchronous with D2; the lack of relict granitic veins in the phyllite unit does not support the latter alternative. The position of intensely deformed retrograde phyllite in the core of the Cattle Creek dome is consistent with the development of
the dome at the margin of a largescale boudin.

An origin for the D2 and D3 deformations based on the flat-lying orientation for foliations in metamorphic rocks although widely related to extensional tectonics is not conclusive as flat-lying foliations have also been documented in contractual settings such as in the lower limbs of nappes in the western Alps [Ramsay et al., 1983]. A contractual setting is difficult to rule out entirely on the basis of field relationships but the problem can be tackled by examining the regional relationships and setting of the Argentine Metamorphics.

5.3 Regional Relationships – Metamorphic Rocks

The Cape River Metamorphics located some 150 km southwest of the Argentine Metamorphics (Figure 2) comprise a substantial tract in the western part of the Charters Towers Province. They are similar to the Argentine Metamorphics in terms of rock types, metamorphic grade, structural succession and association with syntectonic granitoid emplacement [Hutton et al., 1997]. An early contractual deformation was overprinted by sub-horizontal intense D2 fabrics which Fergusson et al. [2005] ascribed to extensional tectonics. This in turn was followed by contractual deformation that formed northwest-trending upright folds [Hutton et al., 1997]. D4 of the Argentine Metamorphics, associated with northerly trending structures reflecting east-west shortening, is a comparable structural phase. The Cape River Metamorphics have fewer age constraints than the Argentine Metamorphics. Detrital zircons from metasandstones of the Cape River Metamorphics are typically ~900 Ma or older [Blewett et al., 1998; Fergusson et al., 2007] and only constrain the depositional age to no older than Neoproterozoic. The unit is intruded by plutons of the
Fat Hen Creek Complex, the oldest of which is affected by the D2 deformation and have U–Pb zircon ages of 493–455 Ma (Figure 11) \cite{Hutton et al., 1997}. $^{40}\text{Ar}^{39}\text{Ar}$ cooling ages for biotite and muscovite for the Cape River Metamorphics are in the range 425–410 Ma which corresponds to erosional exhumation following Early Silurian contraction expressed as the final contractional deformation also evident in the Hodgkinson – Broken River Fold Belt to the north \cite{Fergusson et al., 2005}.

The Anakie Metamorphic Group located south of the Charters Towers Province within the Anakie Inlier (Figure 1), represents exposure that is probably indicative of widespread concealed basement throughout much of central Queensland \cite{Withnall et al., 1995}. It also has a similar lithological content and structural succession to the Argentine Metamorphics. \cite{Fergusson et al., 2005} have reinterpreted the major subhorizontal S2 foliation developed in the Anakie Metamorphic Group as reflecting extensional tectonics. An upper limit to the timing of deformation of the Anakie Group is provided by several K/Ar ages on metamorphic cooling and S2 foliation development of ~500 Ma \cite{Withnall et al., 1996}. The youngest detrital zircons from the upper part of the succession are ~510 Ma \cite{Fergusson et al., 2001} and therefore deformation is constrained to an interval of 510–500 Ma implying a much shorter deformational history compared to that of the Charters Towers Province.

Our data from the Argentine Metamorphics more concisely define the tectonic history of the Charters Towers Province with implications for the Early Paleozoic metamorphic basement throughout northeastern Australia. In summary, basement formed from a primary succession with deposition continuing up until the earliest Late Cambrian at 500 ± 4 Ma followed by contractional deformation and low-pressure metamorphism at ~495 Ma (Late Cambrian) using the timescale of \textit{Gradstein and Ogg} \cite{2004}. This was followed by a major episode of extensional tectonics from ~490 to 460 Ma as demonstrated by U-Pb zircon ages
for plutonic rocks in the Argentine Metamorphics. East-west contractional deformation possibly around 440 Ma in the high-grade part of the Argentine Metamorphics appears to have been of only local significance with regional uplift and metamorphic cooling demonstrated in the latest Ordovician to Early Silurian by $^{40}\text{Ar}/^{39}\text{Ar}$ cooling ages for the Cape River Metamorphics and syntectonic conglomeratic wedges in the southwestern Hodgkinson – Broken River Fold Belt [Arnold and Henderson, 1976; Withnall and Lang, 1993; Fergusson et al., 2005; data herein].

5.4 Regional Relationships – Upper Crustal Rocks

The southern part of the Charters Towers Province, the Mount Windsor Subprovince [Henderson, 1980], is dominated by a latest Cambrian to Early Ordovician succession of sedimentary and volcanic rocks comprising the Seventy Mile Range Group [Henderson, 1986]. This is a succession of deep marine origin that includes a thick unit of silicic lavas and pyroclastic rocks overlain by a mixed unit of silicic to mafic volcanics and volcanioclastics in turn overlain by a thick lithic sedimentary succession. The age of the upper part of the group is well established from graptolitic horizons above the main silicic volcanic unit that are of Early Ordovician (Lancefieldian to Chewtonian) age [Henderson, 1983]. Given that a thick volcanic and sedimentary interval occurs below the fossiliferous rocks, the lower part of the Seventy Mile Group must extend into the Late Cambrian. Deposition of the group therefore ranges from at least ~495 Ma to ~470 Ma (Figure 11) using the timescale of the Gradstein and Ogg [2004].

The Seventy Mile Range Group occurs well to the south of the Argentine
Metamorphics. However they do abut the Cape River Metamorphics (Figure 2) but contact relationships are difficult to resolve because of the intensity of late contractional deformation that affects the Cape River Metamorphics and in this area the Seventy Mile Range Group which for most of its extent is only weakly deformed. Volcanic and hypabyssal rocks of the main part of the Seventy Mile Range Group have a magmatic signature consistent with an extensional backarc setting [Henderson, 1986; Stolz, 1995]. Volcanic rocks within the oldest, unfossiliferous sedimentary part of the Seventy Mile Range Group, the Puddler Creek Formation, have geochemical affinities of an alkaline intraplate association [Stolz, 1995], like the mafic schist in the lower-grade part of the Argentine Metamorphics [Hutton et al., 1997]. Syndepositional normal faulting has also accompanied deposition of the Seventy Mile Range Group [Berry et al., 1992].

Thus the Charters Towers Province in the latest Cambrian to Early Ordovician (∼490 Ma to ∼460 Ma) had regional flat-lying foliation development in an extensional setting in the mid to lower upper crust accompanied by extensional backarc volcanism and sedimentation in the supracrustal rocks of the Seventy Mile Range Group (Figure 12). The province is characterized by voluminous plutonic phases that comprise the Lolworth and Ravenswood Batholiths, with the Late Cambrian to Late Ordovician Macrossan Igneous Province [507 to 455 Ma, Hutton et al., 1997] represented by dominantly granodiorite but ranging to gabbro and tonalite. The age of this suite overlaps with that of the metamorphic assemblages and the Seventy Mile Range Group (Figure 11).

These relationships are consistent with extensional thinning of the lithosphere whereby the supracrustal zone experienced rifting and broadscale basin formation [McKenzie, 1978] whereas deeper crustal levels experienced enhanced thermal gradients, high-T/low-P metamorphism and thermo-mechanical weakening within a pure shear regime (Figure 12).
Large plutons, like that intruding the southeastern margin of the Argentine Metamorphics which has an exposed area of some 100 km$^2$ and is doubtless more extensive beneath Devonian sedimentary cover, generated predominantly in the extensional regime enabled thermal energy to be transported upwards in the crust and encouraged the development of high-T/low-P metamorphic assemblages [e.g., Caggianelli and Prosser, 2002].

### 5.5 Gondwanan Context

Along the Australian sector of the Pacific-facing margin of East Gondwana it has been argued by Direen and Crawford [2003] that rifting and continental separation at $\sim$600 Ma resulted in the development of a passive volcanic margin. This newly developed passive margin is considered the site of deposition for some of the successions preserved in northeastern Australia (e.g., lower Anakie Metamorphic Group [Fergusson et al., 2001]) and associated mafic igneous activity [Withnall et al., 1995]. In contrast at least five episodes of rifting, associated sedimentation and minor volcanism occurred between 827 Ma and 520 Ma in the Adelaide Fold Belt of southeastern South Australia with continental separation hypothesized at 700 Ma [Preiss, 2000]. An older age of continental separation in the Adelaide Fold Belt is consistent with an age of 668 ± 1 Ma for gabbroic rocks associated with the Beardmore Group of the Central Transantarctic Mountains and $\sim$670 Ma detrital zircons in the Koettlitz Group of Southern Victoria Land [Goodge et al., 2002, 2004a]. Given the association of inferred rift-related mafic volcanism and sediments with detrital zircons of 600–570 Ma age in the Anakie Metamorphic Group [Withnall et al., 1995; Fergusson et al.,]
2001], a single continental fragmentation event to form East Gondwana is not viable [cf. Pisarevsky et al., 2003]. Alternatively, fragmentation of a supercontinent was followed by separation of one or more continental ribbons from parts of the East Gondwana margin, such as northeastern Australia.

In the Middle Cambrian to Early Ordovician interval, Australia was part of the recently amalgamated Gondwana continent formed from merger of East and West Gondwana, which coincided with the development of an active margin along the Pacific-facing side of Gondwana [Boger and Miller, 2004]. Contractional deformation is evident in the Middle to Late Cambrian along much of the Ross-Delamerian orogenic belt (Figure 11)[Stump, 1995; Preiss, 2000]. The Delamerian orogeny is considered to have affected eastern Australia between 520 Ma and 490 Ma, and includes events such as fold-thrust belt development in the western Adelaide Fold Belt with low-pressure metamorphism and contractional deformation in the eastern Adelaide Fold Belt [Preiss, 2000; Crawford et al., 2003]. In Tasmania, ophiolite emplacement and high-pressure metamorphism in the Delamerian Orogeny at 515–508 Ma was followed by post-collisional extension at 508–495 Ma including magmatism [Foster et al., 2005]. In the Ross Orogen of the Transantarctic Mountains, relatively long-lived contractional deformation has been prominent (Figure 11).

In northeastern Australia, contractional deformation associated with this convergence is constrained to ~495 Ma (Figure 11), in contrast to southeastern South Australia where Delamerian contractional deformation began around 514 ± 5 Ma [Foden et al., 1999] and continued into the Late Cambrian with an upper constraint provided by late undeformed plutons at 490–485 Ma (Figure 11)[Haines and Flöttmann, 1998]. Extensional tectonics occurred to the east in the Lachlan Fold Belt where Middle to Late Cambrian (520–495 Ma) volcanic inliers contain rocks of backarc association [Foster et al., 2005] and exhumation of
the Moornambool Metamorphic Complex at its western margin also attributed to extensional
tectonics is dated at ~500 Ma [Miller et al., 2005]. Short-lived contraction in northeastern
Australia was followed by extensional tectonics in a continental backarc setting that
continued from ~490 Ma to ~460 Ma (i.e. latest Cambrian to the Middle/Late Ordovician
boundary). This extensional event is not recognized in South Australia and East Antarctica
but coincides with tectonic events in the Lachlan Fold Belt. The first phase of volcanic
activity associated with the Macquarie arc in the eastern Lachlan Fold Belt occurred at
~485–480 Ma followed by renewed activity at ~470 Ma (Figure 11)[Glen et al., 1998; Butera
et al., 2001; Packham et al., 2003]. During this interval widespread Early to Middle
Ordovician deposition of the vast ‘Bengal Fan-type’ turbidite deposits was more-or-less
continuous in the Lachlan Fold Belt and inundated Middle to Late Cambrian island arc and
backarc crust that developed outboard of the Ross-Delamerian orogenic belt [Fergusson and
Fanning, 2002; Crawford et al., 2003]. Early Ordovician extensional tectonics in the
Australian part of East Gondwana is also indicated by extensional deformation in amphibolite
facies rocks of the Harts Range in central Australia [Hand et al., 1999].

The role of extensional events during the Early to Middle Cambrian in association with
Ross-Delamerian orogenesis has been emphasized by Squire and Wilson [2005]. They argued
that a major short-lived (2 Ma) extensional event at ~515 Ma interrupted Early Cambrian
contraction and affected the entire Pacific margin of East Gondwana. This event was related
to roll-back of the subducting plate with development of juvenile arc boninitic and tholeiitic
mafic volcanic basement, in the sense of Stern [2002], in the Lachlan Fold Belt, Northern
Victoria Land, Tasmania, New Zealand and the Ellsworth Mountains of West Antarctica
[Squire and Wilson, 2005, figure 5]. While the formation of these volcanic rocks is well
constrained at several sites (e.g., the southern Heathcote greenstone belt of central Victoria
and Wellington greenstone belt at Wellington River in eastern Victoria), in most places volcanism is only poorly dated and is indicated as only pre-latest Cambrian by fossils in the upper part of the overlying pelagic sedimentary succession [e.g., VandenBerg et al., 2000].

Hornblende gabbro in the Dookie complex of the northern Mount Wellington greenstone belt, in central Victoria, has a U-Pb zircon age of 502 ± 0.7 Ma [Spaggiari et al., 2003] equivalent in age to a less widespread extensional event identified by Squire and Wilson [2005] at 505–500 Ma and indicating that the juvenile island arc basement of the Lachlan Fold Belt was not constrained to one extensional event at ~515 Ma. Ti-poor ophiolitic rocks of the Weraerai terrane in the southern New England Fold Belt have U-Pb zircon ages of ~530 Ma [Aitchison et al., 1992; Aitchison and Ireland, 1995] and these ages imply that there was a protracted and probably dispersed development of juvenile island arc sea floor in the Pacific Ocean outboard of the Ross-Delamerian active continental margin. Contraction has been interrupted by extension along parts of the Pacific margin of East Gondwana such as during deposition of the ~525 to 515 Ma Kanmantoo Group in an extensional basin that transected the ancient passive margin in southeastern South Australia [Preiss, 2000]. For much of the East Gondwana active margin, it is clear that convergent deformation in the Ross-Delamerian orogenic belt and extensional tectonics in the adjoining Pacific realm were synchronous, analogous at a smaller scale to the present-day Taiwan island arc collision and extension in the Okinawa trough [Hall, 2002]. This is shown in several reconstructions from 520 Ma to 460 Ma where extensional regimes co-exist with contractional deformation along the Pacific margin of Gondwana (Figure 13).

The post-extension, early Silurian contraction recognized herein as a widespread event in north Queensland broadly correlates with shortening in the Lachlan Fold Belt dated as occurring between 460 and 420 Ma [Foster et al., 1999].
5.6. Conclusions

Metamorphic rocks in the Townsville region of northeastern Australia represent a continuation of the Ross-Delamerian orogenic belt that formed along the paleo-Pacific margin of Gondwana in the Cambrian to Ordovician. These rocks are an assemblage of siliciclastic metasedimentary and metaigneous rocks with widespread amphibolite and include mafic breccia with a minimum depositional age indicated by a U-Pb zircon age of 500 ± 4 Ma. They were affected by poly-phase deformation with an accompanying metamorphic episode reaching amphibolite facies conditions with anatexis in higher grade rocks. The first deformation was contractional and considered related to widespread convergent deformation along the active Gondwana margin in the Late Cambrian. The second deformation produced intense originally flat-lying foliation and is constrained to an age of ~490 Ma to ~460 Ma by two U-Pb zircon ages (480 ± 4 Ma and 461 ± 4 Ma) for granites affected by and postdating the main foliation respectively. This deformation was synchronous with deposition further south of late Cambrian to Early Ordovician sedimentary and volcanic rocks with a backarc extensional tectonic affinity and therefore we interpret the flat-lying foliation (D2 deformation) as a result of extensional tectonics [e.g., Pavlis and Sisson, 1993]. This extensional episode was concurrent with the development of widespread juvenile island arc and oceanic backarc crust in southeastern Australia and continuing convergent deformation along the Ross-Delamerian orogenic belt. Final contractional deformation affected the higher grade part these metamorphic rocks during long-lived uplift, widespread retrogression and inferred metamorphic cooling.
Acknowledgments. Research funds were provided by the Australian Research Council (grant number A00103036), with additional support from James Cook University, the University of Wollongong and the Geological Survey of Queensland. We are grateful to the Australian Army for allowing access to the Argentine training area. David Carrie made many excellent thin sections. Peter Johnson computer drafted the figures. We thank Damien Foster for assistance with metamorphic aspects during revision of the manuscript. Comments and suggestions on the initial manuscript by two anonymous reviewers resulted in a much improved manuscript.

[2003], Middle to Late Cambrian extensional island arc and backarc basement of the southern Lachlan Fold Belt [VandenBerg et al., 2000; Spaggiari et al., 2003], Tasmania – FC = Forth Complex – 512 ± 5 Ma, HRC = Heazlewood River Complex – 515 ± 7 Ma, FMC = Franklin Metamorphic Complex – 508 ± 8 Ma, extensional episode with Mt Read Volcanics and 40Ar/39Ar ages of metamorphic cooling at 507–508 Ma [Foster et al., 2005 and references therein], Northern Victoria Land – 40Ar/39Ar ages 500–460 Ma with peak of Granite Harbor intrusives at 480 Ma [Dallmeyer and Wright, 1992; Stump, 1995], Southern Victoria Land – U-Pb ages for gneissic and weakly foliated granites – 531 ± 10 Ma, 516 ± 10 Ma, 505 ± 9 Ma, 502 ± 9 Ma, 499 ± 6 Ma [Allibone and Wysoczanski, 2002], U-Pb ages 505–480 Ma from metamorphic rims on zircons [Wysoczanski and Allibone, 2004], the Central Transantarctic Mountains – youngest detrital zircon ages – 505–495 Ma, youngest detrital mica ages – 504 Ma, 510 Ma, 516 Ma and 518 Ma [Goodge et al., 2002, 2004a, b]. Timescale after Gradstein and Ogg [2004].

Figure 12. Schematic cross section for part of the Charters Towers Province towards the end of extensional deformation at ~460 Ma. The upper crust was dominated by the Seventy Mile Range Group which formed by sedimentation and volcanic activity in an extensional setting. Extension was accommodated in the upper crust by subsidence, deposition, shallow intrusions and some syndepositional faulting [Henderson, 1986; Berry et al., 1992]. In the
middle to lower crust extension was accommodated by pure shear [McKenzie, 1978] with widespread development of flat-lying foliation and associated recumbent folds (not shown). Uplift of metamorphic rocks to the surface was a result of younger extensional and contractional deformation that affected in the region in the Early Silurian and Late Devonian to Late Carboniferous [Henderson, 1980].

Figure 13. Reconstructions of the active Pacific margin of Gondwana. Regions with extensional tectonics shown by diverging arrows; regions with contractional deformation are used to infer the location of continental margin subduction zones. For 520–500 Ma the location of subduction zones in the juvenile arc/island arc region of southeastern Australia is not shown as their location and dip is unknown. For 480 Ma and 460 Ma the Larapintine Seaway is a shallow sea that extends across Australia to the Pacific Ocean in the east. Subduction is shown dying out from south to north although it is likely that outboard subduction zones existed in the Pacific near East Antarctica and are obscured in West Antarctica. For 460 Ma the subduction zone in southeastern Australia reflects the development of several microplates and subduction zones outlined by Foster et al. [1999].

<td>Well developed foliation and/or compositional layering with aligned mica, elongate quartz, amphibole</td>
<td>( S_1 ) synchronous with metamorphism - aligned biotite, muscovite, actinolite, and hornblende indicating greenschist to amphibolite facies</td>
<td>Throughout, but harder to find in higher grade rocks</td>
</tr>
<tr>
<td>( \text{D}_2 ) ( S_2, F_2, L_2 (S_2 - S_1 ) intersection lineation), ( L_m ) (mineral lineation)</td>
<td>( S_2 ) dips moderately to gently southward (average orientation of 45°/136°, Fig. 5a), ( F_2 ) and ( L_2 ) plunge moderately to east-southeast (Fig. 5b), ( L_m ) plunges moderately to southeast (average trend of 60°/140°, Fig. 5c), orientation of ( L_2 ) has probably been modified by ( \text{D}_2 ) strain with stretching towards ( L_m )</td>
<td>Abundant tight folds in ( S_1 ) and quartz veins, ( F_2 ) are typically developed on the hand specimen scale with the largest having half-wavelengths of 0.2 m, folds are rounded to tight</td>
<td>Zonal crenulation cleavage especially at lower grades with microlithons up to 1-2 cm thick, lithological layering commonly transposed subparallel to ( S_2 ), extension within foliation plane shown by boudinaged quartz and granitic veins</td>
<td>( S_2 ) synchronous with metamorphism - aligned biotite, muscovite, actinolite, and hornblende indicating greenschist to amphibolite facies</td>
<td>Throughout</td>
</tr>
<tr>
<td>( \text{D}_3 ) ( \text{AS}_3 (\text{Axial Plane}), F_3 )</td>
<td>( \text{AS}_3 ) are recumbent to gently inclined (Fig. 5d), ( F_3 ) trends are west-northwest to east-southeast (Fig. 5e)</td>
<td>Close to tight, recumbent, verge to south, disharmonic, developed at mesoscopic scale only, stumpy shapes (low amplitude-to-wavelength ratios)</td>
<td>No ( S_3 ) axial planar foliation</td>
<td>Some granitic dykes affected by ( F_3 )</td>
<td>Higher grade rocks only, mostly around locality of Argentine south of Cattle Creek dome</td>
</tr>
<tr>
<td>( \text{D}_4 ) ( S_4, F_4 )</td>
<td>Steep north-trending ( S_4 ) with variably plunging ( F_4 ) (Fig. 5f, g)</td>
<td>Broad to tight, low amplitude-to-wavelength ratios, developed at hand specimen scale but range up to folds with wavelength of 2 m</td>
<td>Poorly developed axial planar foliation in ( F_4 ) hinges, ( S_2 ) reactivated as ( S_4 ) on limbs of ( F_4 ) hinges</td>
<td>Veins of leucogranite ascribed to anatexis are both folded by ( F_4 ) and cut across ( F_4 ) axial planes indicating that high-grade metamorphism progressed beyond deformation</td>
<td>Higher grade rocks only, particularly in the western part of the Argentine area</td>
</tr>

</tbody>
</table>

Notes: 1. Uncertainties given at the one σ level.
   2. Error in FC1 Reference zircon calibration was 0.57% for the analytical session
   (not included in above errors but required when comparing data from different mounts).
   3. f_{206} % denotes the percentage of $^{206}Pb$ that is common Pb.
   4. Correction for common Pb made using the measured $^{238}U/^{206}Pb$ and $^{207}Pb/^{206}Pb$ ratios
   as outlined in Williams [1998] and references therein.

</table>

I) Errors are one sigma uncertainties and exclude uncertainties in the J-value.

ii) Data are corrected for mass spectrometer backgrounds, discrimination and radioactive decay, but not isotopic interferences.

iii) Interference corrections: \((^{36}\text{Ar}/^{39}\text{Ar})_{\text{Ca}} = 2.79(±0.05)\times10^{-4}\); \((^{39}\text{Ar}/^{37}\text{Ar})_{\text{Ca}} = 6.82(±0.05)\times10^{-4}\); \((^{40}\text{Ar}/^{39}\text{Ar})_{\text{K}} = 2.86(±0.06)\times10^{-2}\)

iv) J-value is based on an age of 1072 Ma for Hb3gr hornblende [Turner et al., 1971].
