Post-fire recovery of eastern bristlebirds (*Dasyornis brachypterus*) is context-dependent

Abstract

In late December 2003, a wildfire in the Jervis Bay region of New South Wales burned through an area that previously supported a large population of the endangered eastern bristlebird (*Dasyornis brachypterus*). The eastern bristlebird has been described as fire-sensitive, and fire is implicated in the decline of the species. The frequency of occurrence of bristlebirds was investigated in the second week after the fire in a range of sites varying in fire intensity. Bristlebirds were found in burned habitats but were less common in the sites that were more intensely burnt. Bristlebirds had been surveyed along transects in this area two months before this fire and were surveyed again 1, 9 and 13 months after the fire. Compared with prefire numbers, bristlebird numbers decreased in burnt areas after the fire and increased in unburnt areas. This pattern was evident for up to nine months after the fire, after which bristlebird numbers returned towards prefire levels in both burnt and unburnt vegetation. This is in contrast to some previous research on bristlebirds and fire. We suggest that bristlebirds avoided the fire by moving to unburnt areas and returned later when conditions were more suitable. We consider that the apparently slight impact of this fire on bristlebirds was due to the close proximity of unburnt habitat and other refuges. The response of bristlebirds and presumably other birds to fire is likely to be strongly context-dependent, so fire management may be able to be designed so as to be compatible with the conservation of local bristlebird populations.

Running Head: Eastern Bristlebird Response to Fire.

Abstract

In late December 2003, a wildfire in the Jervis Bay region of NSW burned through an area that previously supported a large population of the endangered eastern bristlebird (*Dasyornis brachypterus*). The eastern bristlebird has been described as fire-sensitive, and fire is implicated in the decline of the species. The frequency of occurrence of bristlebirds was investigated in the second week after the fire in a range of sites varying in fire intensity. Bristlebirds were found in burned habitats but were less common in the sites that were more intensely burned. Bristlebirds had been surveyed along transects in this area two months prior to this fire and were surveyed again 1, 9 and 13 months post-fire. Compared with pre-fire numbers, bristlebird numbers decreased in burnt areas after the fire and increased in unburnt areas. This pattern was evident for up to nine months post-fire, after which bristlebird numbers returned towards pre-fire levels in both burnt and unburnt vegetation. This is in contrast to some previous research on bristlebirds and fire. We suggest that bristlebirds avoided the fire by moving to unburnt areas and returned later when conditions were more suitable. We consider that the apparently slight impact of this fire on bristlebirds was due to the close proximity of unburnt habitat and other refuges. The response of bristlebirds and presumably other birds to fire is likely to be strongly context-dependent, so fire management may be able to be designed so as to be compatible with the conservation of local bristlebird populations.

1 **Introduction**

2

3 Fire has been present in Australia since the Tertiary Period (Kemp 1981) and much of the
4 flora of Australia has evolved characteristics that allow survival after this disturbance
5 (Gill 1981). Much of Australia's fauna has also evolved with the influence of fire,
6 resulting in a range of responses from avoidance to exploitation (Keith *et al.* 2002;
7 Whelan *et al.* 2002). The variation in response to fire among Australia's fauna can be
8 explained by a combination of life history, biology and fire regime (Whelan *et al.* 2002),
9 and escape behaviours are expected to become less effective as the size, frequency or
10 intensity of fire increases.

11

12 Many species, including some bird species, take advantage of post-fire conditions. Loyn
13 (1997) found that birds that feed in open ground, such as the flame robin (*Petroica*
14 *phoenicea*), scarlet robin (*Petroica multicolor*), buff-rumped thornbill (*Acanthiza*
15 *reguloides*) and superb fairy-wren (*Malurus cyaneus*), thrived for three years post-fire by
16 exploiting low shrub regrowth. Some insectivores and raptors respond immediately, to
17 take advantage of easy hunting of prey disturbed by fire (Woinarski and Recher 1997).

18

19 The change in population size after a single fire cannot be viewed as indicating a 'typical'
20 response, because response will depend on specific fire characteristics such as intensity
21 and extent, the time since the previous fire and on long-term fire histories (Bradstock *et*
22 *al.* 2005). For example, variation in response to fires was recorded in the splendid fairy-
23 wren; there was no direct mortality as a result of a fire after a six-year fire-free period
24 (Rowley and Brooker 1987), but two more fires in the ensuing three years each caused a
25 decline in numbers (Russell and Rowley 1993).

26

27 There are species that are fire-sensitive because they are unable to avoid the direct effects
28 or they depend on resources that are removed by fire, such as dense vegetation. For
29 example, the rufous bristlebird (*Dasyornis broadbenti*) was not recorded in the area of a
30 single large fire in eastern Victoria until two years post-fire (Reilly 1991). Western
31 bristlebirds (*Dasyornis longirostris*) took 2 - 6 years to recolonise moister areas after a

Post-fire recovery in Dasyornis brachypterus

1 fire, and up to 14 years to recolonise some drier areas (Smith 1987; Burbidge 2003).
2 Another fire-sensitive species, the noisy scrub-bird (*Atrichornis clamosus*) took 4 - 10
3 years to begin recolonising burnt areas (Danks 1997).

4
5 Both individual wildfires and altered fire regimes have been identified as threats facing
6 many species in Australian birds (Garnett and Crowley 2000). Of Australia's 155
7 threatened bird species, 47% have wildfire and/or inappropriate fire regimes identified as
8 current threats to their long-term survival (Garnett and Crowley 2000). The eastern
9 bristlebird (*Dasyornis brachypterus*) is listed as threatened in all jurisdictions of its range:
10 nationally endangered under the *Environment Protection and Biodiversity Conservation*
11 *Act 1999*, endangered in New South Wales under the *Threatened Species Conservation*
12 *Act 1995*, endangered in Queensland under the *Queensland Nature Conservation Act*
13 *1992* and threatened in Victoria under the *Victorian Flora and Fauna Guarantee Act*
14 *1988*. The main threats have been identified as habitat loss and fragmentation, introduced
15 predators, and inappropriate fire regimes (Garnett and Crowley 2000; DEC 2004).

16
17 The eastern bristlebird is a cryptic, ground-dwelling, insectivorous and semi-flightless
18 passerine. It is described as fire-sensitive, based primarily on the work of Baker (1997;
19 2000; 2003). From various studies, Baker (2003) concluded that fire was implicated in
20 the extinction of at least 12 populations of eastern bristlebirds in the last three decades.
21 Fire temporarily removes dense understorey vegetation, which is a critical component of
22 the preferred habitat of the eastern bristlebird. Being semi-flightless and cover-dependent,
23 the eastern bristlebird is not expected to be able to colonise new areas readily or to
24 recolonise areas after disturbances (Smith 1977; Baker 2000). Being semi-flightless may
25 also expose the species to higher mortality during fires.

26
27 Various studies of fire responses of eastern bristlebird populations have shown an array
28 of results. Eastern bristlebirds were known from 11 sites in 1978 near Mallacoota in
29 Victoria but by 1994, as a result of fires, eastern bristlebirds were only found at 1 of those
30 11 sites (Clarke and Bramwell 1998). In 1992, Lamb (1993) surveyed 88 eastern
31 bristlebird territories that had been defined in 1989 near the New South

Post-fire recovery in Dasyornis brachypterus

1 Wales/Queensland border and found that only 36 % of them contained birds. Declines in
2 these populations on the NSW/QLD border have been attributed to inappropriate fire
3 regimes (Hartley and Kikkawa 1994; DEC 2004). In the populations in south east NSW,
4 after five fires within 13 years at Barren Grounds Nature Reserve, eastern bristlebird
5 densities increased with increasing time since last fire from zero birds to approximately 2
6 birds per 5 hectares after 11 - 16 years (Baker 1997; 2003). At Booderee National Park,
7 Pyke *et al.* (1995) found no significant difference between the numbers of eastern
8 bristlebirds detected in habitat 0-7 years post-fire and habitat 13-14 years post-fire. At
9 Nadgee Nature Reserve, large-scale wildfires in 1972 and 1980 burnt most of the eastern
10 bristlebird habitat. By seven years post-fire, eastern bristlebirds had colonised only a few
11 of the areas burned in 1980 (Woinarski and Recher 1997). Baker (1997) proposed that the
12 Nadgee population was, at that time, recovering from near extinction after the fire in
13 1980 because the two fires had left few unburnt refuges.

14

15 In late December 2003, a wildfire burned through approximately 3000 ha of Booderee
16 National Park and adjacent parts of NSW on Bherwerre Peninsula at Jervis Bay on the
17 New South Wales south coast (Fig 1). It was estimated that Bherwerre Peninsula at that
18 time had population of eastern bristlebirds in excess of 700 (D. Bain and J. Baker,
19 unpublished data). The eastern bristlebird was being surveyed here prior to 2003 as part
20 of other research. This fire provided an opportunity to examine the direct effects of a
21 summer wildfire on eastern bristlebirds, because two transects had been surveyed two
22 months prior to the wildfire and parts of them were affected to different degrees by the
23 fire. Thus, there was the opportunity to estimate eastern bristlebird numbers after fire in a
24 range of locations of varying fire intensity and different distances to unburned vegetation.
25 The aims of this study were to determine the effects of fire intensity on the eastern
26 bristlebird population in the immediate aftermath of the fire, and to estimate changes in
27 the population over the first 13 months post-fire.

28

1 **Materials and methods**

2

3 *Post-fire survey*

4 Within 2 weeks of the fire, call playback throughout the burnt area was used to elicit calls
5 from eastern bristlebirds. Ninety-two playback points were surveyed in 3000 ha of burnt
6 vegetation (Fig 1). Areas known to have supported eastern bristlebirds before the fire
7 were targeted for playback. At each call playback point, a tape of eastern bristlebird
8 'duets' was played for two minutes, followed by a five-minute listening period. All
9 eastern bristlebirds heard or seen were recorded, and their location estimated. Due to
10 variation in landscape and burnt vegetation characteristics, some playback locations were
11 only approximately 100 m apart. In these cases, a bird was recorded only if one had not
12 been recorded at the previous point, as judged by direction to the call. All eastern
13 bristlebirds heard were assumed to be in the same burnt habitat as the call playback
14 location. Burnt habitat was assessed in a radius of 150 m from the playback point and was
15 grouped into one of four categories:

- 16 1. High-intensity burn: canopy and understorey completely burnt.
- 17 2. Moderate-intensity burn: canopy scorched/burnt but some leaves remaining and
18 possibly green; understorey completely burnt.
- 19 3. Low-intensity burn: canopy with unburnt patches; understorey generally burnt
20 with occasional patches unburnt.
- 21 4. Burnt edge: any burnt habitat within 150 m of the fire boundary.

22

23 A χ^2 contingency analysis was used to test the hypothesis that the frequency of
24 occurrence of eastern bristlebirds after the fire was independent of fire intensity category.
25 Some of the call playback locations were on the same transects as the following study but
26 these studies were not conducted at the same time so the call playback was not expected
27 to interact with the following listening surveys.

28

29 *Before-and-after surveys*

30 Two transects affected by the 2003 fire, one 4.5 km, the other 3.4 km long had been
31 surveyed two months prior to the wildfire. Both transects were within 800 m of what

Post-fire recovery in Dasyornis brachypterus

1 became the edge of the burnt area, with neither penetrating into the middle of the burnt
2 area (Fig 1). These two transects were subsequently surveyed 1, 9 and 13 months after the
3 fire. Surveys involved a standard listening technique used previously in eastern
4 bristlebird research (Baker 1997; Bain and McPhee 2005). At each survey period,
5 transects were walked slowly, at 2-4 km/h, and the locations of all eastern bristlebirds
6 heard or seen were mapped. The direction and distance of an eastern bristlebird call can
7 be mapped reliably by a competent observer (Bain and McPhee 2005).

8

9 The transects were divided into segments based on the condition of the post-fire
10 vegetation. Each segment was classed as either burnt, burnt edge, or unburnt. The 'burnt
11 edge' category consisted of burnt vegetation at the fire boundary. At each survey period,
12 transects were walked on four separate mornings within four weeks, with the direction of
13 travel reversed each time. The survey (of the four conducted) that had the maximum
14 number of records was used in data analysis, as this number represents the maximum
15 number of birds 'known to be alive' for that transect over that survey period. As surveys
16 utilised call vocalisations as the method of detection, we assumed that there was no
17 difference in detectability between burnt and unburnt habitat.

18

19 There were two segments in vegetation classified as 'burnt' two in 'unburnt' and three in
20 'burnt edge'. A repeated measures, general linear model was used to test the hypotheses
21 that eastern bristlebird numbers changed over time and that the nature of the change
22 depended on the location of the birds in relation to burnt vegetation. The burnt edge
23 category was not independent of the other two categories, as it is adjacent to them both.
24 Therefore, the burnt edge category was not included in this analysis but analysed alone
25 for any influence of time since fire on eastern bristlebird numbers.

26

27 There was only one pre-fire survey in this study. However, the variability of eastern
28 bristlebird numbers before the fire was expected to be low because numbers in one of
29 these transects, which were estimated several times over two years prior to this study,
30 only varied between 2.4 and 2.5 birds/500 m (D. Bain, unpublished data).

31

1 FIGURE 1

2

3 **Results**

4

5 *Post-fire survey*

6 The occurrence of eastern bristlebirds in the second week after the fire was dependent on
7 fire intensity ($\chi^2_3 = 11.8$, $P < 0.01$). The frequency of survey sites with birds present was
8 much lower in intensely burnt areas than less intensely burnt areas. In the areas burnt
9 with high-intensity, eastern bristlebirds were recorded in only 4 % of sites but in the areas
10 burnt with low-intensity, eastern bristlebirds were recorded in 50 % of sites (Table 1).

11

12 TABLE 1

13

14 *Before-and-after surveys*

15 The impact of the fire on eastern bristlebird numbers over the 15 months from the pre-fire
16 survey to 13 months post fire was different in burnt and unburnt vegetation categories
17 (Fig 2). The interaction between survey period and burn category was significant ($F_{3,6} =$
18 8.1 , $P = 0.016$). Table 2 outlines the repeated measures tests performed.

19

20 Over the time-span between two months before the fire to one month after, there was a
21 marked decrease in eastern bristlebird occurrence in burnt vegetation, from 2.18 ± 1 (sd)
22 to 1.35 ± 0.5 birds/500 m. In unburnt vegetation, there was a large increase from $0.58 \pm$
23 0.8 to 2.35 ± 0.5 birds/500 m over this same time span. This interaction between survey
24 period and burn category was significant during this period ($F_{1,2} = 40.1$, $P = 0.024$)
25 (Table 2).

26

27 From 1 to 9 months, there was very little change in eastern bristlebird numbers in either
28 burnt or unburnt vegetation categories. By months 9 to 13, numbers in the burnt
29 vegetation had increased to more than pre-fire numbers and numbers in the unburnt
30 vegetation had returned towards pre-fire numbers. The interaction between survey period
31 and burn category during this period was not statistically significant ($F_{1,2} = 7.6$, $P =$

1 0.111) (Table 2). It is noted that if numbers of birds in both the burnt and the adjacent
2 burnt-edge categories are combined, then by 13 months post-fire numbers had only
3 returned to 75% of pre-fire numbers, not the 121% of the burnt category alone. The likely
4 interaction between the burnt-edge category and the other two burn categories makes this
5 difficult to interpret.

6

7 There was no significant effect of survey period on numbers of birds in the vegetation
8 category 'burnt edge' ($F_{3,6} = 1$, $P = 0.469$) (Table 2). This burn category showed the most
9 variability in eastern bristlebird numbers over the 15 months (Fig 2).

10

11 FIGURE 2

12

13 TABLE 2

14

15 Discussion

16

17 Fire intensity influenced the frequency of occurrence of eastern bristlebirds at Booderee
18 National Park. Two weeks after the fire, the more intensely burnt areas had fewer eastern
19 bristlebirds than the less intensely burnt areas. In forests in south-eastern New South
20 Wales, Smith (1989) found a similar relationship for 10 bird species that are associated
21 with dense understorey shrubs. There were fewer records in the more intensely burnt
22 areas for species such as the white-browed scrubwren (*Sericornis frontalis*) and brown
23 thornbill (*Acanthiza pusilla*). A similar relationship has also been described for the
24 western bristlebird, where individual birds survived a mild-intensity fire but mortality
25 occurred in a more intense wildfire (Burbidge 2003).

26

27 Fire was followed by a decrease in eastern bristlebird numbers in the burnt and burnt
28 edge sites. This probably reflects the mortality and displacement of birds that often
29 occurs in recently burned habitat (McFarland 1988; Smith 1989; Burbidge 2003). The
30 concomitant increase in density in unburnt habitat suggests that some eastern bristlebirds
31 moved from burnt to unburnt habitat, and avoided the burnt habitat for some months.

*Post-fire recovery in *Dasyornis brachypterus**

1 Burbidge (2003) found that western bristlebirds survived some milder fires and
2 subsequently set up home ranges in nearby unburnt vegetation. The findings of the
3 present study suggest that this may also happen after higher-intensity fire.

4
5 Prior to the fire, eastern bristlebird densities varied between the sites. In particular, the
6 unburnt sites had very few birds. This may be due to differences in habitat attributes,
7 although all sites were located in a continuous stretch of habitat that appeared not to
8 differ among sites. This low density in the unburnt habitat almost certainly contributed to
9 the results of this study. These low-density, unburnt areas may have provided eastern
10 bristlebirds escaping fire with available habitat to occupy before returning to pre-fire
11 home ranges. The differences in pre-fire densities between the burnt and unburnt sites
12 impose limitations on the generalities of this study. The low number of replicates in this
13 study almost certainly contributed to high variance in eastern bristlebird densities among
14 sites.

15
16 It is generally considered that good quality habitat occupied by territorial species will be
17 saturated (Newton 1992). This suggests that individuals forced to move into occupied
18 habitat would be resisted by residents. However, results from this study implied that
19 individuals escaping the fire resided, albeit temporarily, in occupied unburnt habitat. Two
20 explanations may account for this observation. As outlined above, the unburnt habitat
21 may have had habitat attributes, which led to it not being saturated. Furthermore, eastern
22 bristlebirds are not considered an aggressively territorial species, having highly
23 overlapping home ranges (Baker 2001), and thus, individuals moving to unburned areas
24 may not have been excluded.

25
26 Although the differences between burnt and unburnt vegetation from 9 to 13 months post-
27 fire were not significant, the return towards pre-fire numbers of eastern bristlebirds from
28 1 to 13 months post-fire may represent the return of displaced individuals back to pre-fire
29 home ranges or dispersal of juveniles following breeding season (Higgins and Peter
30 2002). As there were more birds in unburnt vegetation than before the fire (Fig 2), all
31 available unburnt habitat may have been filled, so the adjacent burnt habitat may be the

*Post-fire recovery in *Dasyornis brachypterus**

1 only area available to juvenile birds. Larger sample sizes may have distinguished whether
2 these changes were significant.

3
4 The numbers of eastern bristlebirds in the burnt edge category were more variable than in
5 the other two burn categories, at each of the time periods (Fig 2). This variation may
6 reflect movement of eastern bristlebirds across the boundary between burnt and unburnt
7 vegetation following the fire.

8
9 There are examples of birds returning to previously occupied sites soon after a fire.
10 Woinarski and Recher (1997), for example, reported silvereyes (*Zosterops lateralis*)
11 foraging in burnt habitat within minutes of an intense fire that burned a relatively small
12 area. In a low to moderate intensity fire in heathland near Sydney, birds avoided flames
13 by moving to adjacent unburnt habitat then immediately returned after the fire had passed
14 (Recher and Christensen 1981). At a longer time frame, marked white-browed
15 scrubwrens and inland thornbills (*Acanthiza apicalis*) were re-caught in the same areas in
16 the months after fuel reduction burns in Karri and Jarrah forests (Wooller and Brooker
17 1980; Wooller and Calver 1988). In the present study, the changing patterns of eastern
18 bristlebird abundance suggest that eastern bristlebirds took over nine months to return to
19 original areas post-fire, perhaps spending the winter and non-breeding season surviving
20 in areas other than their pre-fire home ranges.

21
22 The apparently short-term impact of the fire on eastern bristlebird occurrence on
23 Bherwerre Peninsula after one year differs from the results from Barren Grounds Nature
24 Reserve (Baker 1997; 2003), which implied that fire can devastate eastern bristlebird
25 populations and recovery of the population may take over ten years. However, Pyke *et al.*
26 (1995) found that fire-age did not have a significant effect on eastern bristlebird
27 occurrence at Booderee National Park, although his sample sizes were small and results
28 were confounded by the proximity of unburnt vegetation.

29
30 We suggest that the presence of nearby unburnt habitat for a refuge is an important
31 landscape component for the survival of eastern bristlebirds following fire; a concept

Post-fire recovery in Dasyornis brachypterus

1 suggested previously (Pyke *et al.* 1995; Baker *et al.* 1997; Baker 1997). As with the work
2 of Pyke *et al.* (1995), the two transects we used were close to the fire boundary, due to
3 the opportunistic nature of this study. The greatest distance between a surveyed eastern
4 bristlebird and the fire boundary was only 900 m. The eastern bristlebird is capable of
5 travelling at least 300 metres per hour during daily activities (Baker and Clarke 1999).
6 Post-fire, there were numerous lightly burned and unburnt patches of vegetation
7 throughout the study sites, as a result of fire and topography (Whelan 1995) which could
8 potentially serve as refuges.

9

10 Lack of suitable refuges due to frequent burning are likely to be devastating. It is
11 possible that the difference in eastern bristlebird response between Barren Grounds and
12 the Booderee studies is the high fire frequency combined with the area of each burn at
13 Barren Grounds. The fire in Booderee National Park was the first large fire in 32 years. In
14 1972/73, about half of the Park burned and, since then, there has been a series of only
15 small fires, many of which were prescribed fuel-reduction burns (Pyke *et al.* 1995; Taws
16 1998). In contrast, there have been five large fires, each burning 10-50% of available
17 habitat at Barren Grounds Nature Reserve during 1979-1991 (Baker 1997). Similarly,
18 after large-area fires in 1972 and 1980 burnt most of the eastern bristlebird habitat in
19 Nadgee Nature Reserve, eastern bristlebirds had only colonised a few of the burnt areas
20 after seven years (Woinarski and Recher 1997).

21

22 Studies have reported little impact of a single fire on populations of some small bird
23 species such as superb fairy-wrens, after a fire-free period of many years (Rowley and
24 Brooker 1987). However, frequent fires were shown to have caused declines in the same
25 population (Russell and Rowley 1993). Cowley (1974) also found that individuals of two
26 small cover-dependent passerine species, brown thornbills and white-browed scrubwrens
27 managed to survive a single high-intensity fire and continued to use the same areas as
28 before the fire.

29

30 The observed recovery of the eastern bristlebird population at Booderee National Park
31 compared to Barren Grounds and Nadgee Nature Reserves may have been facilitated by

*Post-fire recovery in *Dasyornis brachypterus**

1 lower predation pressure. While it is suggested that fire can increased predation (Recher
2 and Christensen 1981; Brooker and Brooker 1994; Loyn 1997) intensive baiting of foxes
3 (*Vulpes vulpes*) since 1999 at Booderee National Park and immediately after the fire in
4 2003 (Nick Dexter pers. comm.) may have reduced predation by this species. However,
5 it would have had no effect on native predators such as snakes, goannas and birds of prey
6 or on some other feral predators such as cats and rats. The interaction between feral
7 predator control and post-fire responses of cover-dependant species such as the eastern
8 bristlebird requires investigation.

9

10 There were differences in impacts to eastern bristlebird occurrence as a result of different
11 fire intensities. There were also differences in the reported impacts to and recovery of
12 eastern bristlebird populations after fire from different studies at Barren Grounds Nature
13 Reserve and Jervis Bay. The results of this study support a statement by Bradstock *et al.*
14 (2005) that the response of a species to fire will be highly variable and strongly context-
15 dependent. Post-fire trends can not be viewed as repeated responses, even in two sites
16 which have the same time elapsed since last fire, as fire histories of the sites are almost
17 certainly going to be different along with the intrinsic landscape features and vegetation
18 features of the habitat (Bradstock *et al.* 2005).

19

20 The response of eastern bristlebirds to fire in this study was unexpected. The results
21 suggest that eastern bristlebirds may survive fire if in proximity to unburnt vegetation and
22 refuges and following fire, can survive amongst recently burnt vegetation. The results
23 suggest that cover-dependant birds may escape fire by temporarily moving to nearby
24 unburnt vegetation and then return when conditions are suitable.

25

Management issues

27 Eastern bristlebirds live in fire-prone vegetation and fire management is of high priority
28 in many of these areas for property protection and conservation. The general
29 recommendations for eastern bristlebird management is currently fire exclusion (Baker
30 2000). However, in many areas this is not satisfactory for other fire management goals
31 such as property protection. It may also be inappropriate for other species of co-occurring

*Post-fire recovery in *Dasyornis brachypterus**

1 fauna or flora which may prefer more open vegetation. The results of the present study
2 indicate that the impact of fire on eastern bristlebirds should be further investigated to
3 help address the environmental and social conflicts that are present in and around eastern
4 bristlebird habitat.

7 **Acknowledgements**

8

9 We thank staff at Booderee National Park for organising access to the park following the
10 fire and Ken Russell from the Statistical Consulting Service at the University of
11 Wollongong for helping with the statistical analysis of the results. This research was
12 carried out in association to a larger research project, in accordance with animal ethics
13 approval from the University of Wollongong and scientific permits from the Dept. of
14 Environment and Heritage, Booderee National Park, and the NSW Dept. of Environment
15 and Climate Change. This work was supported by an ARC Linkage Grant with the NSW
16 Department of Environment and Climate Change as the industry partner.

Post-fire recovery in Dasyornis brachypterus

1 **Table 1: Comparison among fire categories in the numbers of sites with eastern**
2 **bristlebirds.**

3 Surveys were conducted two weeks post-fire and the number of eastern bristlebirds
4 expected was obtained from a contingency table. Surveyed column indicates the total
5 number of sites surveyed in each fire intensity category.

6

Vegetation category	Sites with birds	Expected	Surveyed
High-intensity	1	6	24
Moderate-intensity	11	9	35
Low-intensity	8	4	16
Burnt edge	3	4	17
